PREFACE

It seems like only a few short months since we co-edited *The Corsini Encyclopedia of Psychology and Behavioral Science*. We have now compiled the materials for the "Concise" edition of these volumes. In this edition, we have asked previous authors to update their material to reflect the most recent ideas and research findings on their topics. This edition also contains new entries because the fields of psychology and neuroscience continue to flourish. Although each entry is shorter than those of the four volume Encyclopedia, we trust they are thorough enough to be informative to the reader. Numerous authors have referred to other publications relevant to their entries in this book, and we trust these will be useful to the reader in gathering additional details about the topics of interest. The purpose of the Encyclopedia is to provide succinct summaries of information regarding the most important topics in Psychology and Neuroscience for the reader. We hope this concise edition will make that material available to an even wider audience.

We would like to thank our numerous contributors (about 800) who have provided materials for this book. Although deciding on topics to be included and collating and editing the entries is an extensive undertaking, it is the authors who have provided the actual information in the book, and to them we are extremely grateful. We are also grateful to Alinne Barrera, our Managing Editor, for her excellent attention to detail in monitoring the entries as they came and went and for corresponding with the numerous contributors to the volume. We are also grateful to Wade and Margaret Craighead for their assistance in managing various details of keeping us on track in the production of this book. Finally, we are grateful to the staff at John Wiley & Sons, particularly former Wiley editor Jennifer Simon, and current Vice President and Publisher Peggy Alexander for their support of this project and bringing the book into existence, and to Kelly Franklin who brought us to Wiley in the first place.

A

ABNORMALITY

From time immemorial, individuals have recognized a small minority of members of their societies as psychologically "abnormal." The research of Jane Murphy (1976) further demonstrates that people in non-Western cultures, such as the Yorubas of Nigeria and the Yupic-speaking Eskimos of Alaska, readily recognize certain behaviors as abnormal. Moreover, many of these behaviors, such as talking to oneself, are similar to those regarded as abnormal in Western society. Murphy's findings suggest that the concept of abnormality is not entirely culturally relative.

Nevertheless, these observations leave unanswered a crucial question: What is abnormality? Surprisingly, a definitive answer to this question remains elusive. In this entry, we examine several conceptualizations of abnormality and their strengths and weaknesses. All of these conceptualizations strive to provide a definition of abnormality that encompasses both physical and mental disorders, although most place primary emphasis on the latter.

The first and most radical conception examined here is that abnormality is entirely a function of societal values. According to this *subjective values* model, which has been championed by Thomas Szasz (1960), abnormal conditions are those deemed by society to be undesirable in some way. Although this model touches on an important truth—namely, that many or most abnormal conditions are perceived as undesirable—it does not explain why many socially undesirable behaviors, such as rudeness, laziness, and even racism, are not perceived as pathological. A comprehensive definition of abnormality involves more than subjective values. This fact helps to explain in part why Harvard psychiatrist Alvin Poussaint's (2002) recent efforts to include extreme racism in the current diagnostic manual have met with little success.

Proponents of a *statistical* approach, such as Henry Cohen (1981), posit that abnormality can be defined as statistical deviation from a norm. Thus, any behavior that is rare is abnormal. Although this conceptualization is appealing in its simplicity, it suffers from several shortcomings. First, the cutoff points for abnormality are scientifically arbitrary. Should abnormality be defined as the uppermost 1% of the population, the uppermost 3%, or some other figure? Second, a statistical approach provides no guidance regarding which dimensions are relevant to psychopathology. As a consequence, it erroneously classifies high levels of certain socially desirable dimensions, such as creativity and altruism, as abnormal. Third, a statistical approach mistakenly classifies all common conditions as normal. For example, it implies that the bubonic plague ("Black Death"), which killed approximately one third of Europe's population in the fourteenth century, was not abnormal because it was widespread.

Some writers, such as F. Kraupl Taylor (1971), have embraced the pragmatic position that abnormality is nothing more than the set of conditions that professionals treat. According to this view of disorder as whatever professionals treat, psychologically abnormal conditions are those that elicit intervention from mental health professionals. Although this view avoids many of the conceptual pitfalls of other definitions, it does not explain why many conditions treated by professionals, such as pregnancy, a misshapen nose corrected by plastic surgery, and marital conflict, are not per se regarded as pathological.

Advocates of a *subjective discomfort* model maintain that abnormal conditions are those that produce suffering in affected individuals. Although many psychopathological conditions, such as Major Depressive Disorder, clearly produce considerable subjective distress, several others, such as psychopathy (a condition characterized by guiltlessness, callousness, and dishonesty) and the manic phase of bipolar disorder (a condition characterized by extreme levels of elation, energy, and grandiosity), are often associated with minimal subjective distress. Moreover, like the statistical model, the subjective discomfort model provides no guidance concerning what cutoffs should be used to define abnormality. How much discomfort is required for a condition to be pathological?

Most of the aforementioned definitions focus on subjective judgments concerning the presence of abnormality. In contrast, proponents of a *biological model,* such as R. E. Kendell (1975), contend that abnormality should be defined by strictly biological criteria, particularly those derived from evolutionary theory. For example, Kendell argued that abnormal conditions are characterized by a reduced life span, reduced biological fitness (the capacity of an organism to transmit its genes to future generations), or both. Despite its potentially greater scientific rigor relative to other models, a biological model is subject to numerous counterexamples. For example, being a soldier in a war tends to reduce one's longevity but is not a disorder; priesthood (which results in having no children) tends to reduce one's fitness

but is similarly not a disorder. Moreover, a biological model falls victim to the same problem of arbitrary cutoffs that bedevils the statistical model: How much below average must life span or fitness be for a condition to be abnormal?

Whereas some of the preceding conceptualizations of abnormality invoke primarily social criteria, such as value judgments, others invoke primarily biological criteria. Jerome Wakefield (1992) suggests that the proper definition of abnormality requires both social and biological criteria. Specifically, he posits that all abnormal conditions are "harmful dysfunctions." The harm component of Wakefield's conceptualization refers to social values regarding a condition's undesirability, whereas the *dysfunction* component refers to the failure of a system to function as "designed" by natural selection. For example, Panic Disorder is abnormal, according to Wakefield, because (1) it is viewed by society as harmful and (2) the fear system was not evolutionarily designed to respond with intense anxiety in the absence of objective danger. Wakefield's analysis is a significant advance in the conceptualization of abnormality, because it distinguishes those features of abnormality that are socially constructed from those that are scientifically based. Nevertheless, his analysis assumes that all disorders involve failures of psychological or physiological systems. Yet some disorders, such as Post-Traumatic Stress Disorder and perhaps other anxiety disorders, probably represent evolved defensive reactions to subjectively perceived threats. Moreover, Wakefield's analysis presumes the existence of a clear-cut demarcation between adaptive function and dysfunction. But the functioning of many systems, such as the anxiety system, may be distributed continuously, with no unambiguous dividing line between normality and abnormality.

In response to the problems with earlier efforts to provide an adequate definition of abnormality, some authors, such as David Rosenhan and Martin Seligman (1995) and Scott Lilienfeld and Lori Marino (1995), have proposed a *family resemblance* model of abnormality. According to this model, the concept of abnormality cannot be explicitly defined, because abnormality is an inherently fuzzy concept with indefinite boundaries. Instead, conditions perceived as abnormal share a loosely related set of characteristics, including statistical rarity, maladaptiveness, impairment, and the need for treatment. The family resemblance view implies that all efforts to construct a clear-cut conceptualization of abnormality are doomed to failure. Nevertheless, this view implies that there will often be substantial consensus regarding which conditions are perceived as abnormal, because individuals rely on similar features when identifying abnormality.

ACCOMMODATION

The term *accommodation* is used in various areas of study relevant to psychology and neuroscience. Several applications are considered here.

Visual Accommodation

Visual accommodation is the automatic adjustment process by which the lens of the eye adjusts to *focus* on objects at different distances. The lens is a pliant transparent elliptical structure that refracts, or bends, rays of light inward, thus focusing them on the retina. When the eye is at rest, the *suspensory ligaments* hold the lens firmly in a relatively flattened position. The normal resting eye is then in a far-point vision position and can focus on objects that are at least 20 feet (6 meters) distant, without any accommodative adjustment of the lens. Light rays passing through the cornea and aqueous humor then enter the pupil of the eye and pass through the lens, after which they pass through the vitreous humor and reach the retina in focus.

For near vision, closer than 20 feet, accommodation for focusing takes place: The *ciliary muscles,* located around and attached to the suspensory ligaments, contract. This causes relaxation of the suspensory ligaments, which then allow the flattened lens to thicken and bulge, becoming more convex, or rounded. The light rays are thus bent and fall, sharply focused, on the retina.

The ability to focus changes with age. In early childhood, children can focus on objects as close as 2.5 inches (6.3 cen-

timeters). As age increases, accommodation becomes less possible due to progressive hardening of the lens. By 30 years of age, near vision is usually not clear at less than 6 inches (15 centimeters) from the eye. During the 40s, visual articles usually have to be moved farther and farther away in order to be clearly seen. *Presbyopia* is the term given to decreasing ability to focus with advancing age. This leads to the need for near-vision-lensed eyeglasses for most senior citizens for activities requiring close vision. *Hyperopia,* or farsightedness, and *myopia,* or nearsightedness, may also be related to problems of accommodation.

Illumination level has been found to have an effect upon accommodation. There have been various theories of the *physiological mechanism* for accommodation. Some researchers consider the sympathetic nervous system to be responsible for a basic tonal background, through vascular innervation. The oculomotor nerve, through increased or decreased innervation, leads to positive and negative accommodation, or specific adjustment for focusing.

Nerve Accommodation

When a constant stimulus, such as an electric current, is applied to a nerve, the excitability of the nerve under the cathode, or negative electrode, increases quickly. With continued stimulation by current flow, there is a slow decrease in nerve excitability, known as *accommodation,* followed by a sudden drop when the current is stopped. Following cessation of the stimulating current, the nerve briefly becomes less sensitive to stimulation than it was before the current was turned on. Following a resting period, the original level of excitability tends to be restored. During the adaptation period, or time of decrease in excitability, it may be possible to stimulate the nerve by changing either the length or strength of the stimulus.

Accommodation in Auditory Theory

The ear consists of three main divisions: the outer ear, middle ear, and inner ear. The *outer ear* is the portion that allows sound waves to be transmitted, via the *tympanic membrane,* or *eardrum,* to the *middle ear.* In the middle ear are three tiny bones, the *ossicles,* comprising the *ossicular chain.* Here, the sound waves are transduced into mechanical energy, the ossicular chain rocking back and forth. The two tiny muscles of the middle ear, the *tensor tympani* and the *stapedius,* have attachments to the ossicles. The ossicles interface with the *inner ear,* which includes the *cochlea,* a snail-shaped structure that ultimately contains the electrochemical mechanisms for changing the mechanical waves into nerve impulses traveling along the eighth cranial, or *auditory* (*acoustic*), *nerve* to the brain.

The function of the middle-ear muscles has been debated over the years. One of at least five theories has been termed the frequency-selection or accommodation theory. This theory presumes that contraction of the muscles increases the sharpness of hearing by acting as a damping mechanism that selectively absorbs acoustic energy at particular frequencies. The other theories are the intensity-control or protective theory, the fixation theory, the labyrinthine-pressure theory, and a less-accepted theory that the middle-ear muscles are involved in the formation of overtones.

The middle-ear muscles are usually not under voluntary control but contract in response to sound energy in what has been called the *acoustic reflex. Electromyography* has been an important laboratory technique for its study. The acoustic reflex alters the mechanical properties of the middle ear transmission system; *acoustic impedence* is the term given to the consequent mechanical resistance. It may be measured indirectly by audiologists and auditory researchers and has become a notable means of studying hearing in humans for both research and clinical purposes.

Accommodation in Infant Development

The term *accommodation* was also used by Jean Piaget as part of his theoretical view of how infants develop cognitively. Accommodation refers to the infant's modification of concepts or of notions of the world as a response to new experiences or to experiences inconsistent with a previously held notion. *Assimilation* refers to the incorporation into the child's cognitive structure of notions from elements of environmental experience. When an organized cognitive pattern develops through the processes of assimilation and accommodation, a *schema* or *scheme* is said to have developed. Schemata develop, according to Piaget, during the first 2 years, or *sensorimotor period,* during which the infant develops mainly through sensorimotor activities. Piaget differentiated six stages of sensorimotor development.

Piaget's theories have been applied, among other ways, as a partial model of infant and childhood development of language and prelanguage behaviors. With this model, speech-language pathologists and others working with speech and language development can assess very early development for signs of problems. Early intervention aims to aid the prevention of later, larger-magnitude difficulty and thus to promote more adequate functioning later on in areas such as listening, speaking, reading, and writing.

ACHIEVEMENT NEED

The most thoroughly studied of the 20 psychological needs identified by H. A. Murray in his seminal study, *Explo-*

rations in Personality, is what Murray termed "need achievement." In early research studies, the need to achieve (*n Ach*) was assumed to be present in any situation marked by competition with a standard of excellence. (The standard of excellence could of course be set by others' performance or by one's own aspirations.) In most of these studies, especially the ones conducted by D. C. McClelland and his associates, *n Ach* was measured by analyses of stories told by subjects in response to pictures included in or resembling those of the Thematic Apperception Test (TAT). The concurrent validity of the TAT measure was shown by a study in which McClelland and Atkinson found that naval cadets who had been made to "fail" (because of false information given them about their performance on seemingly important tests) introduced more achievement themes in their TAT stories than did members of a control group. The predictive validity of the TAT method was demonstrated by McClelland, who found that college students who made high *n Ach* scores were more likely to enter entrepreneurial occupations in later years than were students who scored low.

McClelland maintained that the level of economic achievement attained by a society is determined by the way it raises its children. This is the theme of his best-known work, *The Achieving Society,* in which he maintained that achievement themes identified in such diverse modes of expression as pottery designs, literature, and children's textbooks predicted levels of economic achievement decades later in various countries and cultures, ancient, medieval, and modern. The effect of child-rearing practices can, however, be reversed. McClelland and Winter report field studies conducted in India of businessmen with initially low levels of *n Ach* who were coached in order to raise their levels of aspiration, and who consequently expanded their business activities and made significant economic contributions to their community.

The work of McClelland and his associates has been criticized on a number of grounds. M. S. Weinstein observed that he, as well as other researchers, found TAT measures to be of low reliability and questionable validity. Maehr and Nicholls objected to the McClelland group's emphasis on personality as a critical variable in determining behavior, to the narrowness of their achievement criteria, and to their failure to obtain significant results regarding achievement motivation in women.

Many researchers have also been unable to find significant relationships between women's *n Ach* scores and achievement-related variables. Horner suggested that women are likely to believe that ambition is inappropriate for them, especially in fields dominated by men, and that, as a consequence, they are inhibited by a "fear of success." Subsequent research by Sid and Lindgren, however, indicated that fear of success has inhibiting effects on men as well as women.

One reason for researchers' inability to relate *n Ach* scores to women's achievement may lie in the way *n Ach* is usually assessed. These measures, both of the TAT and questionnaire type, have typically attempted to cover all components of what has come to be recognized as achievement motivation: task orientation, positive attitudes toward problems and challenges, responsiveness to the Zeigarnik effect, preference for medium-risk ventures (as contrasted with high- or low-risk ventures), competitiveness, and the desire to work independently for self-determined goals rather than for group goals. The unsatisfactory reliability and validity of *n Ach* measures may be the result of attempting to measure too broad a spectrum of traits. Lindgren proposed that problems inherent in such measures could be bypassed by employing a forced-choice questionnaire which would require subjects to choose between achievement-related personal styles and those that were affiliation-related. The rationale for this juxtaposition of factors was found in a number of studies that showed needs for achievement and affiliation to be negatively correlated. Research by Lindgren and by Sadd and colleagues with the resulting questionnaire reported (1) no significant differences between mean scores of men and women undergraduates, and (2) positive correlations between *n Ach* scores and academic performance.

The strong emphasis on cognitive psychology that appeared in the 1970s had a marked effect on achievement motivation research. During this period, Maehr and Nicholls pointed out, researchers became interested in subjects' cognitions about the nature of achievement, their purposes in performing achievement-related acts, and their attributions as to causes of outcomes. Cross-cultural studies, for example, turned up both differences and similarities between national cultures and the way in which their members interpreted "success" and "failure" and attributed the antecedents and consequences of success.

By the early 1980s, the question of whether achievement motivation may be appropriately studied as a personality trait or whether it should be studied cognitively had not been resolved; thus, personality and cognitive psychologists continued to pursue their separate ways. The earlier questions that had been raised by Weinstein as to whether achievement motivation could be measured, or indeed whether it existed at all, seemed to have been resolved, for research activity in this area actually increased during the 1970s and 1980s. Weinstein's criticism of the reliability of TAT measures may, however, have stimulated the development of questionnaire measures, for the majority of studies of achievement motivation in the 1980s employed this potentially more reliable type of assessment.

ACQUIRED DRIVES

One of the raging controversies in the history of psychology once centered on the aspect of the nature-nurture is-

sue, which asks whether motives are inborn or learned. Some psychologists, of whom William McDougall was the most important, took the instinctivist position that motives are inborn, unlearned, universal within species, and—at least to a degree—continuous between species. Other psychologists, for whom John B. Watson was the most important spokesman, argued that motives are acquired through learning and therefore differ from individual to individual, culture to culture, and species to species. As occurred generally with the nature-nurture issue, the intensity of this controversy has lessened with time. It is now clear that all motives are a joint product of biological and environmental forces. If the question is asked at all, it is in terms of the relative importance of these two contributions.

Certain motives, sometimes called *primary drives,* are chiefly biological. Hunger, thirst, pain avoidance, and sex are examples. Even in these cases, however, experience plays a part. Rhythms of feeding and drinking, sensitivity to pain, and preferences in sexual partners are all influenced in this way. Other motives, sometimes called *secondary* or *acquired drives,* are determined primarily by experience, as for instance fears, affection for parents, drug addictions, and functionally autonomous habits such as miserliness. These examples show something of the variety of acquired drives. They also suggest that different acquired drives may depend on forms of learning that differ at least superficially.

Acquisition of Fear

One of the forms of learning just referred to is *classical conditioning.* Experimental evidence that some motives are acquired as the result of this process dates at least to the famous study of Watson and Rayner, who conditioned the boy "little Albert" to fear a white rat. The rat (CS) was shown to the child, simultaneously with a loud and unpleasant sound (US) produced by the striking of a steel bar behind his head. The sound caused the child to cry (UR). After a few repetitions, Albert cried at the sight of the rat (CR), and this fear generalized to other furry objects, such as a fur neckpiece or a Santa Claus mask. Attempts to repeat the Watson and Rayner study were not always successful, and Valentine made the cogent point that fears might be much more easily conditioned to furry objects such as a caterpillar or a rat than to others such as a pair of opera glasses. In spite of these criticisms, the impact of the Watson and Rayner study on the history of psychology was considerable. It indicated that reactions once thought to be instinctive were more properly seen as the result of learning.

Affectional Responses

The young of many species come to treat the first large, moving, noisy object they see as if it were a parent. In most cases this object is in fact a parent, but the process of *imprinting,* as it is called, may produce such attachments to other species and even inanimate objects.

Various lines of evidence indicate that an essential component of imprinted reactions is motivational. The hatchlings of precocial birds, if imprinted on any object, stay near that object and will climb over obstacles to get near it; further, they make distress calls in its absence. The process of learning involved in imprinting bears a strong resemblance to classical conditioning and may be the same thing.

Social Techniques

Literature in the area of acquired motivation suggests that some motives may be acquired by a process that is more like instrumental learning. E. C. Tolman has given us an account that is fairly representative. Figure 1 summarizes his view, which holds that, in infancy, the individual has only a set of biological drives. Inevitably these drives are subjected to frustration, and new techniques are developed to satisfy them. Whatever techniques lead to relief from frustration are learned, and they become characteristic of the individual's repertory of responses to the world. As Tolman's drive-conversion diagram (Figure 1) also suggests, these first primitive adjustments achieved by the individual are not adequate to deal with all situations. They too are frustrated, with the result that new learning occurs and the individual's reactions to the world are modified further.

It should be noted that, so far in this account, nothing has been said about motives. Yet a glance at Figure 1 will reveal that several of the social techniques are ones that we often describe in motivational terms. Aggression, hostility, social approval, loyalty, identification, and self-punishment are all terms that probably occur more often in psychological literature in the context of motive than in that of habit. This suggests that there must be some sense in which habits are, or can become, motives. Gordon Allport once suggested in an article that such is the case, and he offered the concept of functional autonomy, whereby well-established habits become ends in themselves—that is, motives. It should be noted, however, that functional autonomy does not explain such effects; it only describes them.

Addictions

Addictions to tobacco, alcohol, and other substances are of special interest because they dramatize certain features of the psychology of acquired motivation. The motivational power of the addictions is obvious: Lives have been devoted to, and even lost to, activities performed to support an addiction. Established addictions no doubt represent a change in the physiology of the addicted person, probably a change in how certain neurotransmitters function. But at the same time, addictions are clearly acquired. This testifies to the power that experience may sometimes have over biological processes.

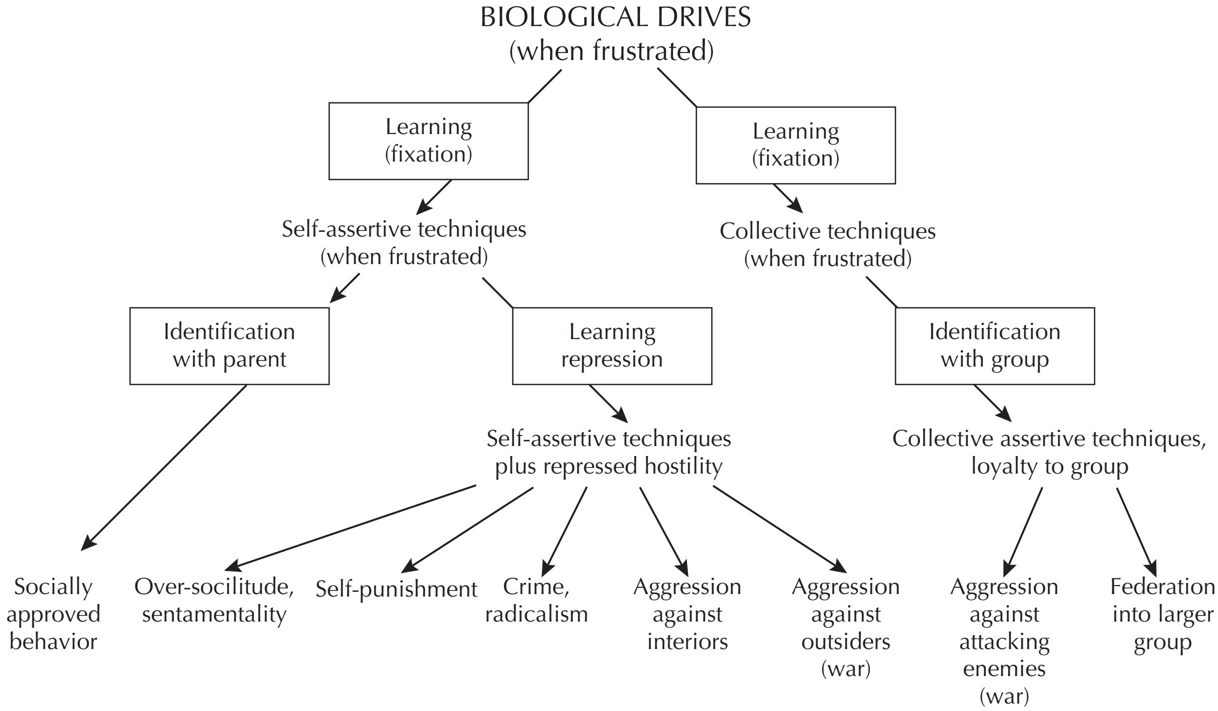

Figure 1. Tolman's drive-conversion diagram.
Source: Figure adapted from G. A. Kimble (1961). Based on E. C. Tomlin (1942).

The mechanism of learning an addiction appears to be a two-stage process. In the first stage, the future addict experiments with the addictive substance out of curiosity or a yielding to peer pressure, or for some other reason that soon becomes irrelevant. In the case of some drugs, like the opiates, only a few such encounters are required to leave the individual with a powerful craving after the initial euphoria produced by the drug wears off. The only ways to relieve this craving are either painful waiting for the craving to subside or taking more of the substance in question. People who become addicted choose the latter alternative, thus beginning the vicious circle: drug—euphoria—agonized craving—drug again. In abstract terms, the learning process appears to be of the operant or instrumental variety, with the relief from craving and the agony of abstinence playing a greater role than the positively reinforcing euphoric experience initiated by the drug.

Motivation and Emotion

The literature on the various acquired drives and drugs provides a particularly straightforward way of making a methodological point. Although common speech and some psychological theories make a distinction between motives and emotions, it is clear that these terms refer to different aspects of the same process. *Motivation* refers to the power of an acquired drive to promote certain kinds of behavior, chiefly those of reaching certain goals—relief from fear, being near a parent, achieving certain social goals, or avoiding withdrawal symptoms. *Emotion* refers to the subjective experiences associated with the arousal of these states.

These points are all very nicely integrated in R. L. Solomon's *opponent-process theory* of emotion. The essential ideas in this theory are the following: (1) the conditions that arouse a motivational/emotional state (State A) also call out a more sluggishly acting opposed state (State B); (2) State B is a "slave" state, which occurs as an inevitable accompaniment of State A; (3) termination of the original emotional circumstances leaves State B as the individual's dominating emotional state; and (4) State B, but not State A, increases with use and decreases with disuse.

Solomon and others have applied this opponent-process theory to many different motivational/emotional reactions. The application provides a rich account of the details of such behavior and a means of understanding the changes in such reactions after many arousals of the emotion. In opiate addiction, for instance, at first the effect of the drug (State A) is a feeling of euphoria, a "rush"; when the drug wears off, its aftereffect (State B) is craving. With continued usage and the strengthening of State B, the effect of the drug is less intense and is often described as a feeling of contentment. Its aftereffect is now much more intense—an excruciatingly painful set of withdrawal symptoms. Similar accounts are put forward for other emotional experiences.

Greg A. Kimble

ACTION POTENTIAL

The action potential is a self-propagating change in membrane voltage conducted sequentially along the axon of a neuron that transmits information from the neuron cell body or sensory ending to the axon terminal. The action potential is initiated either as the consequence of summation of local electronic potentials in the region where the axon arises from the neuron cell body (axon hillock), or as a result of a sufficiently large generator potential in the sensory ending. Once initiated, the action potential is conducted without change in magnitude along the axon until it invades the axon terminal and causes release of quanta of neurotransmitter molecules.

To understand the action potential it is necessary to understand the resting membrane potential. To record the resting membrane potential and the action potential one electrode is inserted into the cell while a second electrode remains outside the cell. The voltage potential between the two electrodes is amplified and measured. For most neurons the measured resting membrane potential is from –60 to –70 millivolts (mV); the inside of the cell is negative relative to the outside of the cell.

The resting membrane potential is determined by the relative distribution of positively or negatively charged ions near the extracellular and intracellular surfaces of the cell membrane. Positive sodium (Na^+) and potassium (K^+) ions and negative chloride (Cl^-) and organic (A^-) ions are important for both the resting membrane potential and the action potential. The positively charged ions are called *cations,* and the negatively charged ions are called *anions.* The organic anions are mostly proteins and organic acids.

During the resting state Na^+ and Cl^- have higher extracellular than intracellular concentrations, and K^+ and A^- are more highly concentrated within the cell. The organic ions never leave the intracellular compartment, and in most neurons Cl^- is relatively free to pass through the membrane. Three factors contribute to determining the ionic distribution across the membrane. The first factor is the relative permeability of the membrane to each ion species. The second factor is the concentration gradient of each ion species. The third factor is the electromotive force created by the separation of charges across the semipermeable membrane.

Because the inside of the cell is negative relative to the outside, and there is a lower intracellular concentration of Na^+, the sodium cations would flood into the cell if the membrane were freely permeable to Na^+. At rest, however, the cell membrane is not freely permeable to Na^+. Permeability of a membrane to any given ion species is controlled by the number of membrane channels available for that particular species. Membrane channels are made of proteins that extend from the extracellular to the intracellular surface of the membrane (i.e., they are membrane-spanning). The membrane channels may be always open, or nongated, or open only under certain conditions. Channels that open or close depending on conditions are called *gated channels.* Whether gated channels are open or closed depends on the conformation of the proteins that form the walls of the channel. When the neuron membrane is at rest the gated channels for Na^+ are closed. The Na^+ that does enter flows through the nongated, nonspecific channels in the membrane, but it is actively extruded from the cell by the sodium-potassium pump. This pump is made of carrier proteins and uses metabolic energy supplied by adenosine triphosphate (ATP). Na^+ and K^+ are linked in transmembrane transportation such that three Na^+ ions are transported out of the cell for every two K^+ ions that are transported into the cell. The Na^+–K^+ pump maintains the intracellular and extracellular concentrations of these ions, which is necessary for homeostatic osmotic equilibrium across the cell membrane as well as creation of the resting membrane potential.

During the resting state the membrane channels do not allow movement of Na^+ into the cell. However, some Na^+ does enter the cell through nonspecific membrane channels. Na^+ does this because it has a higher concentration outside than inside and, therefore, flows down its concentration gradient. Additionally, the electromotive force created by the relative intracellular negativity propels Na^+ inward. The sodium-potassium ATP-coupled pump counteracts the influx of Na^+ ions in the resting state.

The membrane is also not fully permeable to K^+ in the resting state, but K^+ ions are, compared to Na^+ ions, freer to move through the cell membrane. That is, the neuron membrane is more permeable to K^+ than to Na^+. For this reason K^+ moves more readily down its concentration gradient than Na^+, and the resting membrane potential is, therefore, closer to the K^+ equilibrium potential than the Na^+ equilibrium potential.

To summarize, in the resting state the paucity of open membrane channels for Na^+ and K^+ and the Na^+–K^+ pump serve to maintain an excess of extracellular Na^+ and intracellular K^+. The magnitude of the resting membrane potential is the result of the degree of separation of these cations and the presence of the organic anions within the cell. Because the membrane is more permeable to K^+ than Na^+, the resting membrane potential more closely approximates the equilibrium potential for K^+ than for Na^+.

The Na^+ and K^+ channels are voltage-gated. This means that a change in voltage across the membrane changes the conformation of the channel protein to either open or close the channel. If the membrane depolarizes and the membrane potential becomes more positive, the Na^+ channels begin to open. On dendrites and cell bodies, channels are opened by neurotransmitters released at the synapse from other cells. The neurotransmitters bind to receptors on the target neuron and open chemically gated ion channels. If the neurotransmitter is excitatory, the postsynaptic membrane is slightly depolarized in the area of the synapse. This depolarization is less than required for generation of an ac-

tion potential. However, depolarizing excitatory postsynaptic potentials (EPSPs) sum at the axon hillock with hyperpolarizing inhibitory postsynaptic potentials (IPSPs). If the resulting change in membrane polarity at the hillock is a depolarization that exceeds about 10 mV an action potential is initiated.

Depolarization at the axon hillock causes voltage-gated Na^+ channels to open. The number of Na^+ channels opened by the depolarization is proportional to the amount of positive change in membrane potential until threshold for action potential initiation is exceeded, at which time essentially all of the Na^+ channels in the area of threshold depolarization open and Na^+ rushes into the axon. The membrane potential then moves rapidly (about 0.5 ms) toward Na^+ equilibrium potential until it becomes about +55 mV. This is the rising phase of the action potential; when it reaches its peak, Na^+ channels close and voltage-gated K^+ channels open. K^+ leaves the cell and, in combination with decreased Na^+ conductance, reverses the depolarization. The K^+ channels stay open long enough not only to return the membrane potential to its resting level, but to cause a brief (about 2 ms) overshoot hyperpolarization. During the early part of the hyperpolarizing phase of the action potential, Na^+ channels can not reopen and another action potential can not be generated. This is known as the *absolute refractory period.* This prevents action potentials from summating. As the membrane continues to repolarize, an action potential can be generated if a stronger than normal stimulus is applied to the axon. This is known as the *relative refractory period.* Within 2.5 ms after peak depolarization of the action potential, the resting Na^+–K^+ concentrations are restored and the system is ready for reactivation.

The action potential propagates because the ionic current flow at one point of the membrane causes changes in current flow in the adjacent membrane toward the axon terminal. The current flow changes the transmembrane voltage potential and opens Na^+ channels. The entire sequence just described is then repeated. In myelinated axons, the current flow occurs only at the nodes of Ranvier. In addition to lacking the electrical insulation provided by myelin, the nodes of Ranvier also have a far greater concentration of Na^+ channels than do the parts of the axon covered by myelin. The result of the presence of myelin is that the action potential jumps from one node to the next (saltatory conduction). This produces more rapid conduction of the action potential than is possible in nonmyelinated axons.

ADAPTATION

Like many other words in psychology, *adaptation* has multiple meanings. At the basis of all the meanings, however, is the concept carried by its Latin root, *adaptare:* to fit.

Among ethologists, who think that characteristic species-typical behaviors are distillations of evolutionary processes, each physical and behavioral characteristic of a species is the product of and contributes to its adaptive radiation, the multiplication of individuals that can survive in the changing environment, and the diversification of the species in a diverse environment. Such adaptation is genetically based and requires numerous generations to be accomplished.

In contrast to this genetic adaptation are phenotypic adaptations, often only seconds in duration, which occur within the life span of an individual. The results of these adaptations are not transmitted to the offspring, although the capacity for such adaptation is. Implicit in the concept is the alteration of an individual by the presence of a persistent, nontoxic or nontraumatic, nonfatiguing stimulus, or by the prolonged cessation and absence of a customary, persistent stimulus, such as weightlessness. Examples of such adaptation include the gradual diminution in the coldness of water after we immerse our hand in it; the reduction in loudness of a tone after a few seconds; and the return of sight (though colorless) after a period in a darkened room following exposure to bright lights, and the return of comfortable color vision after reexposure to a brightly lighted environment. The mechanisms involved in these examples are all different: stimulus (receptor) failure in the cold; activation of an acoustic reflex (plus receptor change); and bleaching and regeneration of photopigments plus neural change in the retina. In general, scientists tend to think of this kind of adaptation as occurring in or affecting the receptor, whereas the term for a similar phenomenon—*habituation*—is reserved for those situations in which more central events are at least involved if not prominent.

A so-called "General Adaptation Syndrome" was pro-

posed by Selye (1950) as part of our typical response to dangerous environmental challenge. This syndrome is an extension of Cannon's Emergency Syndrome (1932/1960) the "flee, fright, or fight" syndrome, consisting of a rapid total body response to the challenge. Many manifestations of the adaptation syndrome have been observed in lower animals, but they often are difficult to detect in humans. Other concepts (e.g., acclimatization) have been proposed to account for many of the data.

ADDICTION

Addiction is a term widely used to indicate any type of excessive repetitive involvement with an activity or substance, and it is applied as readily to exercise, reading, and television viewing as to alcohol, cocaine, or heroin use. Such broad use of the term detracts from its technical value, and in this entry the term will be used to refer only to substance use. When considering problematic patterns of use, two distinct patterns, abuse and dependence, are described (American Psychiatric Association, 1994). Substance Abuse refers to life problems from substance use—use in situations in which it is physically dangerous, use interfering with occupational roles or with family and other social relationships, or use resulting in legal difficulties. In contrast, Substance Dependence is more syndromal. Physiological components of dependence may include tolerance—the need for increasing amounts of the substance to attain the same behavioral and subjective effects—or withdrawal, a physical syndrome activated by cessation of use of the substance. Behavioral components include using larger amounts of the substance over longer periods of times than intended; spending excessive amounts of time obtaining, using, and recovering from use of the substance; or using instead of engaging in other recreational and social pursuits. Psychological components include continued use despite knowledge of medical or psychological conditions caused or worsened by substance use, and desire or actual attempts to cut down or stop using the substance. Use of a range of substances, including alcohol, other sedative/hypnotic/anxiolytic drugs, cocaine, other stimulants, heroin, cannabis, hallucinogens, inhalants, and nicotine, can lead to Substance Abuse or Dependence. A withdrawal syndrome is associated only with alcohol, sedative/hypnotic/anxiolytic drugs, heroin, and nicotine.

Epidemiology

Use of alcohol is common; regular use or abuse of other drugs is less common (Grant & Dawson, 1999). At some time in their adult lives two thirds of Americans have been regular drinkers (consumed at least 12 drinks in a year). In contrast, just under 16% of Americans are regular drug users (illicit use of a drug at least 12 times in a year) at some point in their lives. The lifetime prevalence of Substance Abuse and Dependence varies by substance, with different prevalence rates for men and women. Alcohol Abuse or Dependence is most common, with a lifetime prevalence for men of 25.5% and for women of 11.4%. In contrast, 8.1% of men and 4.2% of women have had any form of drug abuse or dependence at some time in their lives. The most common drug of abuse or dependence is cannabis, followed by prescription drugs, cocaine, amphetamines, hallucinogens, opiates, and sedatives.

Etiology

The causes of addiction are complex and involve an interplay among three dimensions—the biological, the psychological, and the social. The relative importance of each dimension varies with the specific substance of abuse and with the individual user. Considerable research has attempted to identify the causes of dependence at the cellular or molecular level. A number of different neuronal changes have been suggested as causing Alcohol Dependence, including changes in neuronal membranes, changes in the excitability and function of nerve cells mediated through the calcium and GABA receptor/chloride channels, changes in the activity of excitatory neurotransmitter systems, and changes in second messenger systems (Moak & Anton, 1999). Research on opiate dependence has failed to find changes in opiate receptors associated with addiction. However, at the subcellular level, chronic exposure to opiates has been demonstrated to lead to long-term changes in specific G protein subunits (Stine & Kosten, 1999).

Substance use disorders run in families, and research has attempted to distinguish genetic from familial aspects of etiology. Both twin and adoption studies suggest a heritable component to Alcohol Dependence. With other drugs, some studies are suggestive of genetic elements, such as evidence of common drug preferences in monozygotic twins, and increased risk for drug dependence in families (Hesselbrock, Hesselbrock, & Epstein, 1999). The relationship between family history and the development of alcohol or other substance dependence, however, is not absolute—the majority of offspring from families with Alcohol Abuse or Dependence do not develop problems, and the majority of those with Alcohol Abuse or Dependence do not have a clear family history (Fingarette, 1988).

Among those with familial alcohol or drug problems, the mechanisms by which inherited risk is expressed are not clear. The most common mechanism appears to be through specific temperament or personality—persons high in sensation seeking, low in harm avoidance, and low in reward dependence. Consequently, those with inherited risk for alcohol or drug dependence are at greater risk for Conduct Disorder or Antisocial Personality Disorder.

Psychological research has demonstrated the importance of interactions between the individual and environment. Repeated exposure to drug use situations can lead to conditioned physiological responses to the situations that are similar to physiological responses to the actual drug (Rohsenow et al., 1994). The development of strong positive expectancies about the effects of certain drugs can also contribute to continued use (Brown, Christiansen, & Goldman, 1987). Individuals may use substances to enhance positive moods as well as to cope with negative emotions, and those with other psychological problems are at particularly high risk for the development of substance use disorders as well.

Alcohol and drug use occurs in a social context. Introduction to alcohol and drug use most commonly occurs with either peers or family members. Individuals who are at high risk for using drugs and for other problem behaviors often join with peers of a similarly high risk level, and these peer groups then may influence those within the group to continue to use or experiment with other substances and other high-risk behaviors.

Prevention

Prevention of addiction has taken many forms, including broad-brush prevention programs in schools; prevention targeted at specific populations, such as pregnant women; and environmentally focused interventions that change laws and policies, decrease access to the substance, and increase penalties. Individually and environmentally focused interventions have been successful in preventing or delaying the onset of use, decreasing use among those already using, and decreasing harmful consequences to the individual or to others.

Treatment

Treatment efforts include both psychological and pharmacological approaches. A number of psychological therapies are effective in the treatment of Substance Abuse or Dependence. Brief, motivationally focused interventions are effective for individuals with milder problems, and they also may enhance treatment outcomes when combined with ongoing treatments (Bien, Miller, & Tonigan, 1993). Cognitive-behavioral therapies, including community reinforcement treatment, relapse prevention, social skills training, and behavioral couples therapy, have good support for their effectiveness in treating Alcohol Dependence (McCrady & Langenbucher, 1996). Community reinforcement combined with the use of vouchers (Higgins et al., 1994), and family therapy (Liddle & Dakof, 1995) are effective in treating drug dependence. Outcomes for those who complete long-term treatment in therapeutic communities are good, but dropout rates are high (Simpson & Curry, 1997). Treatments to facilitate involvement with self-help groups such as Alcoholics Anonymous or Narcotics Anonymous also are effective (Project MATCH Research Group, 1997), and continued active participation in self-help groups is correlated with better outcomes.

Separate from medications for withdrawal, effective pharmacotherapies to treat substance use disorders are somewhat limited in number. Naltrexone, acamprosate, and disulfiram have evidence supporting their use in the treatment of alcohol dependence. Methadone, LAAM (1-a-acetylmethadol), and buprenorphine have strong evidence of effectiveness in the treatment of opioid dependence. Nicotine replacement products are effective in the initial phases of treatment for nicotine dependence, and bupropion appears to be effective for longer-term pharmacotherapy (Barber & O'Brien, 1999).

Conclusions

The term *addiction* is overused, but it is useful in referring to a range of substance use problems. Etiology of these problems is complex, with multiple biological, psychological, and social factors contributing. Prevention is possible, and a number of effective treatments are available.

ADHD (ATTENTION-DEFICIT/ HYPERACTIVITY DISORDER)

Description

Attention-Deficit/Hyperactivity Disorder (ADHD) is most commonly characterized by persistent and chronic inattention and/or excessive motor restlessness and impulsive behavior. Earlier names for ADHD included Minimal Brain Dysfunction, Hyperkinetic Impulse Disorder, and Attention Deficit Disorder with or without Hyperactivity. Since the 1994 publication of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*), ADHD has been reorganized into three subtypes: predominantly inattentive (ADHD-I), predominantly hyperactive-impulsive (ADHD-HI), and combined (ADHD-C). The inattentive subtype requires six or more symptoms of inattention and five or fewer hyperactive-impulsive symptoms. The hyperactive-impulsive subtype consists of six or more symptoms of hyperactivity-impulsivity and five or fewer inattentive symptoms. The combined subtype requires six or more out of nine symptoms from both the inattentive and hyperactive-impulsive categories. Symptoms on the inattentive list are related to poor attention and organizational skills, forgetfulness, and distractibility. Symptoms on the hyperactive-impulsive list refer to restlessness, excessive talking, and interrupting. According to *DSM-IV,* the symptoms must be present for at least 6 months and observable by 7 years of age. For the purpose of diagnosis, symptom manifestation should be developmentally inappropriate and exhibited in two or more settings (e.g., home and school).

Prevalence

Prevalence rates of ADHD in the childhood population vary, with expert opinion most often citing an incidence of approximately 3–5% (American Psychiatric Association, 1994). Prevalence rates in adults are more speculative, but are estimated to be about 4.7% (Barkley, 1998). The disorder is more common in males, with Barkley (1998) citing three males to one female for nonreferred samples.

Diagnosis

The diagnosis of ADHD remains difficult, with no single test to assess it and a heavy reliance on subjective measures. A comprehensive evaluation of ADHD in adults or children should assess the presence or absence of symptomatology, differential diagnosis from other disorders that mimic ADHD, and the possibility of comorbid psychiatric disorders. At a minimum, the evaluation should include a clinical interview, a medical evaluation conducted within the past year, standardized behavior rating scales from parents and teachers, and direct observation of the patient. The evaluation for both children and adults includes a family history as well as documentation regarding developmental, social, and academic functioning. An evaluation for adults should also include information regarding their childhood via academic records and transcripts and retrospective-childhood ratings by the adult patient and a parent or another individual who knew the patient as a child. Common conditions that may coexist with ADHD and warrant screening include Oppositional Defiant Disorder, Conduct Disorder, Bipolar Disorder, Antisocial Personality Disorder (for adults), and learning disorders. An assessment of intellectual, academic, neuropsychological, and attentional functioning is desirable for purposes of differential diagnosis, as well as for pointing out individual strengths and weaknesses. Psychoeducational testing can also be useful when a low level of intellectual functioning or a learning disability mimics or coexists with ADHD.

Treatment

Treatment of ADHD should be individualized depending upon the presenting concerns. Treatment approaches may include behavioral interventions combined with medica-

tion. Interventions begin with education about ADHD, its etiology, and its treatment. Behavioral interventions for children include social skills training, school interventions, and parent training in contingency management. Behavioral treatments for adults often focus on developmentally appropriate self-monitoring techniques (e.g., a self-prescribed reward for completing a goal), time management skills, organizational skills, social skills, and vocational counseling. Adults may also choose to have an individual therapist or coach to monitor daily progress.

The use of pharmacological interventions is warranted if the symptoms are interfering significantly with functioning at home, school, or work. Psychostimulant medications (e.g., methylphenidate and dextroamphetamine) are considered safe and effective treatments for ADHD and are used to treat children as well as adults whose diagnoses have been confirmed. Stimulants, typically considered the first line of defense, can produce improvements in impulse control, attention, on-task behavior, and social behavior. A number of new delivery systems for psychostimulant medications have become available that have the potential to reduce dosing from the older regimen of two to three times a day to once a day.

Other medications, including bupropion and tricyclic antidepressants, are considered when there are concerns regarding substance abuse or coexisting depression, or when the stimulants produce significant side effects. There are several new nonstimulant compounds under development for the disorder. These compounds target the norepinephrinergic, histaminergic, and dopaminergic systems.

Neurobiologic Bases of ADHD

The etiology of ADHD is unknown, although the disorder is now considered a disorder of the brain and development. There has been a wave of recent genetic studies that suggest that a substantial genetic component contributes to the disorder. Most of the genetic research has focused on candidate genes involved in dopaminergic transmission.

Dysfunction in both dopaminergic and norepinephrinergic neurotransmitter systems are implicated in ADHD. Both clinical and preclinical pharmacological studies support the role of these neurotransmitters in ADHD, with additional confirmation for the role of catecholamine's involvement arising from the observation that compounds known to improve ADHD symptoms affect catecholamine transmission. Neuroimaging research into brain structure and the function of ADHD in children and adults has shown significant differences between subjects with ADHD and controls in frontal, basal ganglia, and cerebellar anatomy and function. A number of functional imaging studies demonstrate decreased neuronal activity in the anterior cingulate and associated projection areas in subjects with ADHD. A combination of methods using behavioral, imaging, and genetic techniques should increase our understanding of the etiology of the disorder in the future.

ADOLESCENT DEVELOPMENT

Adolescence can be defined as the period in life when most of a person's biological, cognitive, psychological, and social characteristics are changing in an interrelated manner from what is considered childlike to what is considered adultlike (Lerner & Spanier, 1980). When most of one's characteristics are in this state of change one is an adolescent.

Adolescence requires adjustments to changes in the self, family, peer group, and institutions. There are individual differences in the timing, speed, and outcomes of these transitions, changes caused by variation in the timing of connections among biological, psychological, and societal factors, and not merely *one* of these factors acting alone (Brooks-Gunn & Petersen, 1983; Lerner, 2002). A major source of diversity in development is the systemic relations adolescents have with people and institutions in their context (Bandura, 1964; Block, 1971; Douvan & Adelson, 1966; Lerner, 2002; Offer, 1969).

Multiple Levels of Context are Influential During Adolescence

Adolescence is a period of rapid transitions in physical characteristics. The quality and timing of hormonal or other biological changes influence, and are influenced by, psychological, social, cultural, and historical factors (Elder, 1998; Gottlieb, 1997; Magnusson & Stattin, 1998; Tanner, 1991).

Biological effects interact with contextual and experiential factors to influence psychological and social functioning—for example, academic achievement (Lerner, 2002; Lerner & Galambos, 1998; Simmons & Blyth, 1987). Evidence does not support the claim that behavioral disturbances are a universal part of adolescence (e.g., Hall, 1904;

Freud, 1969) or that general psychological or social disruptions mark adolescence. For example, the biological changes of early pubertal maturation have been linked to delinquency in adolescent girls, but only among those who attended mixed-sex schools (Caspi, Lynam, Moffitt & Silva, 1993) or among girls who socialized with older peers (Magnusson & Stattin, 1998).

Changing Relations among Adolescents and Their Contexts Produce Development in Adolescence

The varying relations between adolescents and their contexts constitute the basic process of development in this period and underlie both positive and negative outcomes that occur (Lerner, 2002). Most developmental trajectories across adolescence involve positive adjustment on the part of the adolescent. For most youth there is a continuation of warm and accepting relations with parents (Grotevant, 1998). The most optimal development occurs among youth who are afforded the individual and ecological assets needed not only for positive development but also for thriving (Benson, 1997; Damon, 1997).

Conclusions

To advance basic knowledge and the applications aimed at enhancing youth development, scholarship should be directed toward elucidating the developmental course of diverse adolescents and how their individual and ecological strengths—and those of families and communities—result in healthy, positive development. Policies and programs must be aimed not only at the amelioration or prevention of problems; rather, actions must be directed toward promoting positive youth development (Lerner, Fisher, & Weinberg, 2000).

The stereotype that there is only one type of pathway across adolescence is not viable in the face of current knowledge about adolescent diversity. In future research and applications, scholars and practitioners must extend their conception of adolescence to focus on changing relations between individual youth characteristics and their distinct ecologies. Understanding these relations may enable the strengths of all young people to be translated into actions, resulting in successful contributions to self, family, community, and civil society.

ADOLESCENT SEX OFFENDERS

Historically, sexual offenses by adolescents have been minimized and viewed as innocent sex play, experimentation, curiosity, or a normal aspect of sexual development. In the early 1980s, however, clinicians and the judicial system determined that aberrant juvenile sexual behaviors were unacceptable and would be considered criminal actions in need of appropriate psychological treatment. Although incidence rates vary, Uniform Crime Report (UCR) statistics indicate that 20% of rapes and about 50% of reported cases of child molestation are committed by adolescents. Confirmatory data from treatment settings show that child victims of sexual abuse report an adolescent perpetrator in 40 to 60% of cases. Most adolescent sex offenders are male. The incidence rate is about 5% for females; such offenses predominantly occur with siblings or in baby-sitting situations.

The most common offenses among male offenders are fondling, rape, and exhibitionism, with 50% of the offenses involving some form of penetration. Nearly 66% of the victims are children under 10 years of age. Most of the victims of adolescent sexual offenses are known by the offender; the majority are either family members, extended family members, or acquaintances. It is noteworthy that the majority of adolescent sex offenders had themselves been sexually abused as children or came from families in which spousal violence, child abuse, or sexual molestation had occurred. The high incidence of childhood victimization suggests a reactive, conditioned behavior pattern that demonstrates the cyclical nature of sexual abuse. There is no evidence that adolescent sex offenders are more prevalent in the lower socioeconomic strata, although several studies implicate the problems of the father-absent household.

Earlier studies on the etiologies of juvenile sexual abuse revealed that the adolescent child molester is a loner, has few friends or social peers, prefers interaction with younger children, has a limited occupational history, is an underachiever, is immature, and identifies with a dominating mother. More recent research has suggested other clinical dimensions of the adolescent offender (i.e., feelings of male inadequacy; low self-esteem; fear of rejection; anger toward women; aberrant erotic fantasies; and identification with adult models of aggression, violence, and intimidation). A central characteristic of the offender is poor psychological adjustment and adaptation, which is evident in poor social skills, social isolation, lack of appropriate assertiveness, and deficits in communication skills.

Differential diagnosis is a major concern in the evaluation of sex offenders. It is difficult to distinguish between the diagnosis of "sex offender" and related disorders of delinquency, impulsivity, conduct disturbances, hyperactivity, and Substance Abuse. Frequently, a dual diagnosis seems in order. A related problem arises when clinicians or researchers must differentiate between the psychological and criminal nature of the offense. A review of the literature by G. E. Davis and H. Leitenberg emphasizes that empirical research on the characteristics and profile of the adolescent sex offender is still at the rudimentary stage.

In recent years, several studies have reported on the psychological assessment of juvenile sex offenders versus nonsex adolescent offenders. Studies using the Minnesota Multiphasic Personality Inventory and the Rorschach Inkblot Test found few differences between sex offenders and juvenile offenders. This has led researchers to conclude that adolescent sex offenders are actually a subgroup of juvenile delinquents or sociopaths. On the Rorschach, however, the former group gave more anatomy responses, which reflected repressed hostility and destructive impulses.

An increasing number of rehabilitation programs are now available for the specific treatment of the adolescent sex offender. A National Adolescent Perpetrator Network has been established with guidelines for treatment components and goals. These include confronting denial, accepting responsibility, understanding the pattern or cycle of sexually offensive behaviors, developing empathy for victims, controlling deviant sexual arousal, combating cognitive distortions that trigger offending, expressing emotions and the self, developing trust, remediating social skills deficits, and preventing relapse. In addition, these intensive treatment programs focus on didactic instruction on normal human sexuality, training in interpersonal and dating skills, and the teaching of anger control techniques. Psychodynamic-oriented therapy has shown disappointing results, whereas various behavioral, cognitive-behavioral, and prescriptive approaches have proved to be most efficacious. Many programs use a multicomponent treatment approach, which usually includes family therapy. However, biological treatment modalities such as antiandrogenic medications are not indicated in the treatment of adolescent offenders. Residential treatment and community-based programs are showing much promise. J. Bingham and C. Piotrowski discuss the usefulness and rehabilitative aspects of a house arrest program in Florida as an option to incarceration for young sex offenders. Unfortunately, few controlled outcome studies have been reported on the long-term effectiveness of these types of treatment programs.

ADOPTED CHILDREN

Intra- and Extrafamilial Adoption

A distinction is made between intrafamilially and extrafamilially adopted children. In intrafamilial or kinship adop-

tion, children are adopted either by blood relatives or by family members by marriage, frequently a stepparent of the adopted child. A genuine desire to adopt is, normally, not the primary motivating force in kinship adoptions, except when childless family members adopt. The classical intrafamilial adoption occurs (a) to protect children whose parents are not available to care for them, (b) to prevent children from ever being returned to an unfit parent (addiction, violence, etc.), or (c) to change the legal status of stepchildren. The majority of adoptions are extrafamilial ones, whose goals include building a family (e.g., in the case of infertile couples), balancing a single-gender sibling constellation, or making a foster child or a child in need into a family member. Selfish goals include securing cheap labor, acquiring a permanent baby-sitting service for younger siblings, or, in the worst-case scenario, acquiring a sex object.

Known or presumed reasons for the adoption can play a major role in the parent-adoptee relationship. Complications in stepchild adoptions can be predicted when a child resents the family merger and insists on keeping the biological father's name or when a reluctant stepparent fears adverse financial consequences. Children deal well with unequal status among siblings, if it is a result of the children's own choices. Equal treatment of children in daily life is more important than equality of legal status.

Special Needs Children

Twenty-five percent of domestic adopted children in the United States are reported to be special needs (SN) children. Many parents cannot foresee the impact such children can have on the family. SN children include children with physical or emotional (including behavioral and delinquency) problems. Parental estimates of physically ill or handicapped children's effect on their lives are often more realistic than the outcome projection of adopting children with mental or emotional deficits or handicaps. Families are rarely prepared for the enormous consequences mental illness, acting-out behavior, addiction, and delinquency can have on them. The fact that many of the older adoptees already have multiple rejections behind them further impedes successful bonding and family integration. Family breakups can result from unrelenting stress. Successful outcomes are related to parent/family qualities including flexible expectations, coping and listening skills, resourcefulness, rejection tolerance, sense of humor, willingness to forgive, applause readiness, patience, and love.

Telling Children About Adoption: How and When

Informing children about their adoption status is of major importance. It eliminates the risk that the child might find out from nonfamily sources, which could jeopardize the adoptee's trust in the parents. Where adoption is a familiar, positively valued household subject even before the child grasps the meaning of the word, concept comprehension grows naturally with the child's cognitive development and evokes positive emotions. Even inadvertently portraying adoption as an inferior, last-resort way of building a family devalues the wanted child to a means to an end. Late disclosure, even in adulthood, can seriously affect the adoptee's sense of self and create identity problems.

Acceptance, Rejection, Identification

Depending on their preadoption history, adoptees may experience acceptance, rejection, identification, and separation issues in a magnified way, as these issues can activate concerns about the loss of the biological parents and the reasons for and permanence of their being wanted by their new parents. Identifying with the adopting parents may be a complex task, if truth and fantasy about the lost parents interfere or if strong differences, such as skin color or IQ, set them apart. Parental counteridentification problems can be felt. Not convinced that family bonds are forever, adoptees appear especially vulnerable to even a semblance of rejection. Even normal parental limit setting can be interpreted as a rejection. Being sensitive to weak, unstable, or conditional parent-child bonding, adopted children can act out and seriously test parental love. While actually seeking confirmation of the unconditional acceptance they had hoped for, they sometimes precipitate the very rejection they feared. Children traumatized by the instability of ever-changing caretakers in early childhood may have difficulty bonding successfully and face exceptionally turbulent times when seeking to separate from their parents in adolescence. Reassuring adoptees of having been chosen, not merely wanted, can increase their self-esteem and experience of being secure. A comparison of normal children—both adopted and nonadopted—revealed no difference in self-concept between the two groups. Adoption becomes a negligible factor in individuals who are able to make a positive adjustment.

Search For Biological Parents

Despite the presumed rejection by their birth parents, many adopted children start to search for their biological parents, typically during adolescence. Motivating goals include the wish to meet the parent(s) and additional family members; to learn about their lives; to replace the birth parents' presumed rejection with an acceptable scenario; and to gain genetic information and clarify identity issues. Outcomes can be positive, but adoptees can also uncover parents who are in negative life circumstances or unwilling to enter a personal relationship for fear of destabilizing their present social balance.

Understanding parents assist their adopted children in finding their birth parents. Search interests vary: out of a group of transracially adopted children, all of the Black children, but only some of the Asian and Caucasian ones, initiated a search.

Searches can be hampered by laws governing the disclosure of information on birth parents, some of which are intended to protect not only adoptees but also the privacy of the biological parents.

Open, Closed, and Mediated Adoption

Closed or confidential adoption was standard practice in the past. In response to the psychological problems and genetic information gap caused by this practice, open adoption is becoming the mode of choice, and mediated adoption offers an intermediate solution.

Open adoption refers to information sharing and/or actual contacts between biological and adoptive parents. Communication may be limited to the time before the child is placed with the new parents, or it may continue as long as the parties involved remain interested in maintaining contact. Open adoption offers the opportunity to meet biological relatives or to maintain established ties if the child had lived with biological family members prior to adoption. Children in open adoption situations typically feel less rejected, have higher self-esteem, and adjust better. Changes to reduce or discontinue contact were initiated more often by birth parents than by adoptive families.

It appears wise to allow children who never knew or do not remember their birth parents to meet them early. Very young children take facts as they are and need no explanation. Having one mother who gave birth to the adoptee and another mother to live with is perfectly acceptable, particularly if in the child's mind it has always been that way.

In *mediated adoption* a third party shares information between biological and adoptive families without disclosing identities. Families who are unwilling to reveal their name or whereabouts can share information so as not to deprive the adoptee. Later, the child will be able to initiate contact with the birth mother, if desired. Concerns include possible misunderstandings or misinterpretations regarding birth parent–related information.

Nationally, states that permit open adoption seem to have a significantly higher adoption rate. This suggests that both biological and adopting parents may be more comfortable with having firsthand information about the child's family background or future prospects.

Matchmaking: Facilitating Adoption Informally

In line with open adoption and a less secretive approach to the adoption process, as well as governmental promotion of adoption, two innovative approaches have brought some success. First, children available for adoption are featured on the Internet, which provides broad, even interstate, access to them. The second approach features organized events, such as outings, that give potential parents or families a chance to meet children who are available for adoption in a casual setting. The benefit here is not merely that children receive targeted exposure, but that a setting is created where spontaneous emotional connections can occur and where both sides have a chance to assess compatibility. The drawback is that many children who participate in these get-to-know-each-other parties and repeatedly are not chosen tend to feel like rejects.

Interracial Adoption

In the United States, Caucasian couples willing to adopt outnumber adoptable Caucasian children. This situation is a factor in the increase in interethnic, interracial, and international adoptions. The Multiethnic Placement Act of 1994 outlaws racial or ethnic bias in selections of adoption and foster care placements. Foster parents who have bonded with a child of a different race can no longer be prevented from adopting on racial grounds. Contrary to the objections raised against interracial adoptions, research has shown that no psychological harm came to African American children adopted into White families: They developed a positive racial identity, and their adjustment was excellent. Black adoptees found to have more problems than Whites had been older when adopted and had come from more unstable and abusive backgrounds. While the color of loving parents seems to matter less, interracial adoptees are more comfortable in ethnically and racially integrated schools and communities. These children prefer interracial adoption over being farmed out to foster homes and child care facilities.

International Adoption

Legalized abortion, a decrease in the number of adoptable Caucasian children, social acceptance of single parenthood, and financial support from the government have caused the number of adoptable children in the United States to drop significantly, reportedly by 30,000 in 20 years. Consequently, many couples, especially Caucasian ones, looked for children abroad, including in Asian countries. Most prevalent among foreign adoptees were Korean, Romanian, and Russian children.

Since the Korean War, Korean children have been favorite adoptees, the most sought after for about 30 years. Initially adoptees were war orphans or unwanted Amerasians, and later they were mostly abandoned girls and children born into poverty. As a group they made excellent adjustments, had good self-esteem, and were quiet, high-achieving, responsible, socially mature, and without emotional problems. Although the majority of these children were past the noncritical stages of adoption on arrival in the States, they did better than U.S.-born Caucasian adoptees.

Later, Romanian and, more recently, Russian children became popular U.S. adoptees. In the 1990s, after news reports on neglected and abused children in Romania were broadcast, many U.S. families adopted Romanian children. Most Romanian adoptees had endured serious hardships, including institutionalization, neglect, serious malnutri-

tion at developmentally critical times, and, in some cases, abuse. As a result of social deprivation, many of the adoptees suffered from disinhibited attachment disorder, displaying indiscriminate friendliness with strangers. Many children older than 6 months showed cognitive impairments, but not the younger adoptees. However, some children, though equally deprived during critical phases, overcame their problems. Similar reports came from families with children adopted from Russian orphanages.

Specific parental stress can be created by foreign country officials and government-sanctioned red tape, which can delay the adoption (e.g., through extortion or in an effort to solicit bribes), and can also occur when transplanted children, surrounded by strangers and unable to communicate in English, manifest (at least initially) regressive, anxious, or rejecting behavior instead of the joy and gratefulness the parents naively expected.

Mental Health and Related Issues

Adoptees have been reported to be overrepresented in clinical populations, but there is no evidence that being adopted is a major factor affecting mental health, as attested to by the history of Korean adoptees. Overrepresentation may relate to the fact that parents may more readily refer adoptees to mental health clinics because many have unrealistic expectations about child behavior or because the lack of genetic ties presumably exempts them from a connection to the problem. Although some reports indicate that there is no significant difference between biological and adopted children in prevalence of psychological problems or serious psychopathology, others found that natural children may more often develop internalizing problems, whereas in adopted children problems like lying, stealing, and aggressive and/or sexual acting out predominate. These findings may relate to an adoptee's age at the time of permanent placement. Research suggested that, based on the age at placement, the probability of an adoptee's acting out was found to be as follows: up to 3 months: none; 3 to 12 months: possible; 12 months on: expected. The core issue, though, is not time, but how the time was spent. Exposure to depersonalizing institutions, multiple rejections, or abusive foster care placements, or the experience of being given up for adoption only after becoming unmanageable, tends to intensify any propensity for maladjustment or delinquency and may trigger a mental illness for which biological prerequisites are met. Another etiology of potential problems has been connected to the possibility that at least some adopted children come from an undesirable genetic background, given that many adoptees are conceived and born outside of socially responsible circumstances.

In adoptees who became schizophrenic, genetic lineage, not adoption, was key. Research from Finland showed that a healthy adoptive home safeguards children with a genetic vulnerability to schizophrenia. Even depression could not be tied to adoption. Instead, depression in adoptees was related to individual life events, like friendship problems or personal losses. The problems observed among Romanian and Russian adoptees were related not to adoption but to preceding events.

Overall, mental health problems are not readily tied to adoption. Heredity and environmental circumstances are factors with adoptees as with other children. Even an established factor, like age at adoption, is not the correct indicator for the link to maladjustment. Factors likely to play an etiological role in maladjustment and mental illness, although equally applicable to all children, may be somewhat more prevalent in the adoptable population, with the exception of Korean children.

Identity confusion may be the one condition that can be related directly to adoption. It is difficult to construct a cohesive sense of identity when the initial building blocks consist of negative messages (absent birth family, abandonment, neglectful institutions, rejecting or abusive foster settings), which contradict positive messages from adoptive family, teachers, and social environment, and it is likewise difficult to build on speculations to fill the information gap in cases of closed adoption. Interracial adoptees seeking to identify with their parents gain from concentrating on shared interests and values and on deemphasizing differences in appearance. Fusing confusing and contrasting experiences and knowledge into one coherent entity is the goal of the adoptees' search for an identity congruent with the inner self.

Adoptive Parent Status

Traditionally children were adopted by married couples. Some states eventually allowed single individuals to become adoptive parents. Although the subject remains controversial, there are increasingly more gay and lesbian couples who adopt. However, in some states this is not a legal option. Research to date has not shown any negative effects on the adoptees, either in identification with parents or in influence on the children's sexual orientation.

Government Interest in Adoption

Since the Adoption Assistance and Child Welfare Act (1980) brought about an increase in kinship adoptions, government efforts to promote adoptions overall have increased. In 1998, 100,000 children were reported to be waiting for adoption. The government goal for adoption was set at 56,000 in 2002.

On behalf of adoptable and adopted children, it needs to be noted, *de lege ferenda,* that it must become illegal for governmental authorities and particularly the legal system to disrupt strong psychological bonds between young children and their caregivers. If a parent has not been concerned enough to be cognizant of the existence of a child he fathered, or if biological parents are reconsidering their deci-

sion to give a child up for adoption and demand the return of this child who is now emotionally rooted elsewhere, their claim has to be denied in the interest of the child. The right to maintain strong psychological bonds has to supersede the presumed rights of blood relatives that were never executed to establish firm mutual psychological attachments.

ADRENAL CORTEX

The adrenal glands are located superior to the kidneys and consist of two anatomically and chemically distinct structures: an outer cortical region in which steroid hormones are synthesized, and an inner medullary area in which catecholamines are produced. The cortex is divided into three zones: the zona fasciculata, which secretes glucocorticoids; the zona reticularis, which is responsible for adrenal androgen production; and the zona glomerulosa, which releases mineralocorticoids.

The glucocorticoids represent the end product of the hypothalamic-pituitary-adrenal (HPA) axis and are involved in a myriad of functional responses in the organism. These hormones serve as major regulators of carbohydrate and lipid metabolism, in adaptation to stress; in linking sleep and waking states; in food-seeking and cognitive behaviors; in controlling emotional states; in mediating anaphylactic and immune responses; in modulating the responses to neurochemicals, hormones, and growth factors; and in the differentiation and development of cells (Munck, Guyre, & Holbrook, 1984; Tsigos and Chrousos, 1994). Cortisol is the principal natural glucocorticoid in humans, whereas in many animals corticosterone is the primary glucocorticoid.

Regulation of Glucocorticoid Secretion

The main driving force behind glucocorticoid secretion is corticotropin-releasing hormone (CRH) acting in synergy with arginine-vasopressin (AVP), both of which are primarily released from the paraventricular nucleus (PVN) of the hypothalamus. The CRH stimulates the corticotroph cells in the anterior pituitary to secrete corticotropin (ACTH), which, in turn, influences the adrenal cortex. Three separate regulatory forces are involved in the secretion of glucocorticoids under physiological conditions and during times of stress. A circadian rhythm of basal activity is under the influence of the suprachiasmatic nucleus. Stress-induced responses are more complex and involve afferent inputs from numerous brain regions, including the locus ceruleus and autonomic systems in the brain stem, the amygdala-hippocampus complex, and the cerebral cortex. Finally, a feedback inhibitory input is provided by glucocorticoids.

Circadian Rhythm of Cortisol

In general, changes in plasma cortisol occur in parallel with those of ACTH. The rhythm of ACTH secretion results, in turn, from periodic changes in CRF. Cortisol levels peak in the early morning just prior to awakening, marking the onset of circadian activation. There is a gradual decline throughout the day until it reaches a nadir during early hours of nocturnal sleep, to abruptly rise during the later part of sleep (Van Cauter & Turek, 1995).

Glucocorticoid Secretion Under Stressful Conditions

Living organisms survive by maintaining a complex dynamic equilibrium that is constantly challenged by intrinsic or extrinsic disturbing forces. In response to a stressor that exceeds a threshold magnitude, the organism changes its behavior and physiology to maintain homeostasis. Behavioral adaptation includes increased arousal and alertness, heightened attention, and suppression of feeding and sexual behavior. Concomitantly, physical adaptation occurs and includes functions that redirect energy sources to the stressed body site, where they are needed most. In this adaptive process, glucocorticoids, along with catecholamines, form the frontline of defense.

Glucocorticoid secretion during stress also is dependent upon the release of CRH and AVP, although the magnitude of PVN activity is influenced by the nature and intensity of the stressor. Simultaneously, the locus ceruleus/norepinephrine-sympathetic system (autonomic-arousal system) becomes activated during stress, thus facilitating the release of epinephrine and norepinephrine from the adrenal medulla and the peripheral sympathetic nervous system. The PVN and the autonomic-arousal system are anatomically and functionally connected to each other and to the mesocortical/mesolimbic systems and the hippocampus.

Glucocorticoids and the Pathophysiology of Stress Response. Generally, the stress response, with the resultant elevation of glucocorticoid levels, is meant to last only for a limited duration. The time-limited nature of this process renders its accompanying catabolic and immunosuppressive effects beneficial, with no adverse consequences. Chronic activation of the stress system, however, is detrimental. For example, prolonged exposure to elevated glucocorticoid levels results in suppression of anabolic processes, muscle atrophy, reduced sensitivity to insulin and a risk for diabetes, hypertension, hyperlipidemia, arterial disease, peptic ulcers, amenorrhea, impotence, immunosuppression, and the impairment of growth and tissue repair (Munck et al., 1984). In addition, elevated glucocorticoid levels are associated with psychopathology, neuronal damage, and impaired cognitive function (McEwen, 1994; Tsigos & Chrousos, 1994). An efficient endocrine response to stress is one that is rapidly mobilized in the presence of a threat and ef-

fectively terminated once the threatening condition is no longer present.

Regulation of Glucocorticoid Secretion Through Negative Feedback

Inhibition of glucocorticoid secretion is achieved primarily through the action of glucocorticoids themselves. This negative feedback inhibition is achieved partly by glucocorticoid binding to specific corticoid receptors in the brain. Based on biochemical and functional characteristics, two types of corticoid receptors have been described (Reul & De Kloet, 1985). The glucocorticoid receptor (GR) is widely distributed in the brain but is most abundant in hypothalamic CRH neurons and pituitary corticotrophs. The mineralocorticoid receptor (MR) is densely localized in hippocampal and septal neurons. The MR binds glucocorticoids with a tenfold higher affinity than the GR. The receptor characteristics and distribution complement each other, thus providing the organism with the ability to modulate HPA responses. The MR operates at low glucocorticoid concentrations and exerts a tonic inhibition. When glucocorticoid levels are high, the MR receptors become saturated and the corticosteroids then bind to GR receptors, thereby ensuring a return to homeostasis.

Association Between Glucocorticoid Regulation and Psychopathology

Several lines of research support the association between glucocorticoid regulation and psychiatric disorders (Holsboer, 1989; Tsigos & Chrousos, 1994). Both physical and psychological stressors have been shown to be temporally related to psychiatric illness. Because glucocorticoids are intricately linked to the neurobiology of stress, alterations in glucocorticoid levels and/or activity are expected in association with psychiatric conditions. Indeed, altered HPA function has been shown in a variety of psychiatric disorders, including depression, Anxiety Disorders, Substance Abuse, Anorexia Nervosa, and Schizophrenia. Pharmacological studies indicate that glucocorticoids directly modulate neurotransmitter function and behavioral systems, as well as the activity of psychotropic agents. Moreover, there is evidence that glucocorticoids exert genomic effects in the brain and regulate transcription of many genes, including those that code for behaviorally active neuropeptides. Therefore, a greater understanding of the effects of glucocorticoids at the molecular level, and their interactions with different neurotransmitter systems, should provide important clues into the pathophysiology and treatment of these disorders.

Summary

Because glucocorticoids target almost all organ systems to regulate a myriad of functional responses, alterations in their level and/or activity can lead to diverse functional consequences.

ADULT INTELLECTUAL DEVELOPMENT

Why do some individuals retain their behavioral competence well into advanced old age, whereas others show early decline? This question has long been a central topic in the psychology of adult development and aging. Five central questions and relevant research findings address this issue:

1. Does intelligence change uniformly through adulthood, or are there different life course ability patterns?
2. At what age is there a reliably detectable age decrement in ability, and what is the magnitude of that decrement?
3. What are the patterns of generational differences, and what are their magnitudes?
4. What accounts for individual differences in age-related change in adulthood?
5. Can cognitive decline in old age be reversed?

The Measurement of Adult Intelligence

Most large-scale studies of adult intelligence conducted during the past few decades have used either the Wechsler Adult Intelligence Scale (WAIS), one of its derivatives, or a

derivative of Thurstone's work on the primary mental abilities. Findings of these studies differ markedly, however, depending on whether age comparisons have been made cross-sectionally or whether the same individuals have been followed longitudinally over time.

Differential Patterns of Change

There is no uniform pattern of age-related changes across all intellectual abilities. Studies of overall intellectual ability (IQ) are therefore insufficient to monitor age changes and age differences in intellectual functioning for either individuals or groups. Age difference work with the WAIS suggests that verbal abilities are maintained well, whereas performance tests show early age differences favoring younger adults. Longitudinal data on the WAIS also show high levels of stability of verbal behaviors into advanced old age, whereas performance scores begin to decline in midlife. Studies of the primary mental abilities indicate that active or fluid abilities tend to decline earlier than passive or crystallized abilities. These findings are complicated by ability-by-age and ability-by-cohort interactions. For example, women tend to decline earlier in the active abilities, whereas men do so on the passive abilities. Although fluid abilities begin to decline earlier, crystallized abilities appear to show steeper decrement once the late 70s are reached.

Age Level And Magnitude of Age-Related Intellectual Decline

Cross-sectional studies with the WAIS suggest that significant age differences favoring young adults can be found by the 30s for performance tests and by the 60s for verbal tests. These differences, however, confound cohort effects in education and health status. By contrast, in longitudinal studies, reliably replicable average age decrements in intellectual abilities are rarely found before age 60, but they are observed for all intellectual functions at least by age 74. Analyses of individual differences in intellectual change, however, demonstrate that even at age 81 less than half of all observed individuals showed reliable decremental change over the preceding 7 years.

Generational Differences

The existence of generational (cohort) differences in intellectual abilities has been conclusively demonstrated. Almost linear positive cohort shifts have been observed for inductive reasoning, with more spasmodic positive shifts for verbal ability and spatial orientation. A curvilinear cohort pattern has been found for number skills, which reach a peak for birth cohorts born in the 1920s and then follow a largely negative slope. A similar curvilinear cohort pattern has been observed for word fluency. As a consequence, cross-sectional studies of intellectual aging underestimate age changes before age 60 for abilities with negative cohort gradients and overestimate age changes for abilities with positive cohort gradients.

Individual Differences in Age-Related Change in Adulthood

Individual differences are large at all ages, such that substantial overlap among samples can be found from young adulthood into the mid-70s (cf. Schaie, 1988b). Very few individuals decline on all or most abilities. Indeed, maintenance of functioning on one or more abilities is characteristic for most individuals well into advanced old age. A number of factors account for individual differences in decline, some of which have been shown to be amenable to experimental intervention. Predictors of favorable cognitive aging include (1) absence of cardiovascular and other chronic disease; (2) favorable environment, as indicated by high socioeconomic status; (3) involvement in a complex and intellectually stimulating environment; (4) flexible personality style at midlife; (5) high cognitive status of spouse; and (6) maintenance of level of perceptual processing speed.

Reversibility of Cognitive Decline

Present understanding of individual differences in cognitive decline suggests that unless neurological pathology is present, cognitive interventions may serve to remediate known intellectual decline and reduce cohort differences in those individuals who have remained stable in their own performance over time but who have become disadvantaged compared with younger peers. The effectiveness of cognitive interventions has been demonstrated in various laboratory studies as well as in a recent major clinical trial. Cognitive decline in many older people may well be the result of disuse of specific skills that can be reserved by appropriate training regimens. In two studies, approximately 66% of the experimental subjects showed significant improvement, and about 40% of those who had declined significantly over 14 years were returned to their predecline level.

ADULTHOOD AND AGING: SOCIAL PROCESSES AND DEVELOPMENT

One of the most reliable findings in social gerontology is that with age, people report fewer social partners. Assuming that cultural ageism is responsible, researchers had

construed this phenomenon as society's rejection of older adults. Laura Carstensen's (1999) socioemotional selectivity theory, however, posits that decrease in social network size is a developmental process of social selection that begins in early adulthood. According to the theory, this decrease is the direct result of people's actively reducing the number of peripheral social partners with whom they interact; in contrast, the number of emotionally close social partners stays relatively constant with age. The age-related preference for close social partners, as opposed to acquaintances, is documented in many studies of men and women using ethnicity diverse groups of Americans and samples from Germany, Hong Kong, and mainland China.

Close social partners provide emotionally meaningful interactions, and satisfaction with family members, including siblings, spouse, and children, increases with age. The sibling relationship represents one of the longest, more enduring relationships in life, and Victor Cicirelli's (1989) research reveals that people who report positive relationships with siblings, particularly their sisters, also report lower levels of depression. In addition, the marital tie is also important to overall well-being. Across the life span, marital satisfaction follows a curvilinear pattern: high in the early years of marriage, decreasing slightly into middle adulthood, and then rising again toward the end of middle age. People whose marriages survived into old age report high levels of marital happiness and contentment. Although they reported that difficult times did occur, they attribute their marriage's longevity to strong levels of mutual commitment and friendship.

Children are sources of high satisfaction for parents of all ages. Karen Fingerman's (2003) research reveals that middle-aged mothers enjoy watching their daughters enter adulthood, and older mothers benefit from the intergenerational kinship that their children and grandchildren provide. The relationships between parents and children are marked by reciprocity, with both generations reporting high levels of shared emotional and instrumental support. The type of instrumental support, however, varies by age, such that older parents are more likely to provide financial support, and their middle-aged children are more likely to provide practical assistance.

Although the most emotionally meaningful relationships often include family members, the strain of caregiving can create tension. With the exception of a minority of adults who experience increases in their sense of purpose and life satisfaction, most caregivers experience decreases in well-being. For both men and women, rates of depression are higher among caregivers than the general population, and physical complaints often increase with the added physical and emotional strain of caregiving, especially for those caring for a family member with a dementing illness. These family caregivers are most often women—wives, daughters, or daughters-in-law. When men are caregivers, they often receive more instrumental help but less emotional support from friends and family members than their female counterparts.

The majority of research has focused predominantly on the insular traditional family group of children and parents, but the definition of family is changing, and Vern Bengtson (2001) has written about several influences that are altering the picture of family relationships and age. With greater longevity, intergenerational connections will become more important to family members to fulfill emotional and practical needs. In addition, higher rates of divorce and remarriage introduce understudied unions that will also influence social networks of older adults. Finally, non-European-American family systems often include extended kin networks, and the importance of these family members has been relatively ignored in the literature.

In addition to family members, friends play a significant role in social processes and well-being across adulthood for both men and women. Although findings are conflicting, men generally report larger social networks than women, and women's friendships are marked by greater intimacy, mutual self-disclosure, and greater emotional support. Men often report less satisfaction with their friendships than women, but the greater emotional bonds women experience may also be detrimental: Women are more likely to report more burden from their friendships than men.

Friendships comprise many different types of associations, from casual relationships to more intimate, collaborative, and enduring bonds. Friends serve as confidants, model coping strategies, enhance self-esteem, and buffer stressful life events. Although friendships are important for all age groups, research by the laboratories of Antonnuci, Levitt, and Carstensen indicates that types of relationships vary in importance over the adult life span. Young adults tend to have many friends and a wide circle of affiliations, and happiness is related to larger networks comprised of many acquaintances. By middle adulthood, people selectively reduce their number of friends and form close, long-term relationships with those remaining in their network. In late adulthood, as spouses and old friends die, maintaining relationships with close friends becomes especially central to well-being. Karen Rook's (1995) work, however, emphasizes that older adults also rely on companions for recreational activities, even if these casual friends do not provide emotional support per se.

Whether with family or friends, social connection is necessary and essential to overall well-being. Having meaningful relations is associated with decreased reactivity to stressors, greater immune functioning, decreased risk of some diseases such as hypertension, faster recovery from illness, lower chances of relapse, and even lower risk of mortality. In fact, measures of social support, such as the absence or loss of social ties, are as important in predicting mortality as other known medical indicators, such as cholesterol level and smoking history. Social connection is also important to emotional well-being, including lower rates of

depression, anxiety, and sleep disturbance. Of course, not all social interactions are beneficial. Karen Rook's research indicates that negative social exchanges have stronger associations with well-being than do positive social exchanges. Such findings clarify the importance of positive social relations on well-being, and the potential risks incurred by negative exchanges.

Current knowledge suggests that social processes do not diminish in importance across the adult life span. For every age group, social connections are necessary for physical and mental well-being. Developmental processes, however, alter the structure and meaning of social relationships; over time, the number of social partners decreases, but the meaning of close friends and family members becomes even more central to the daily lives of older men and women.

AFFECT

Affect is typically considered to reflect the feelings associated with emotional processes, which are related in presently unknown ways to the other major components of emotions—expressive, autonomic, and cognitive. Affective experience has been among the most difficult aspects of mind to understand scientifically because it is so thoroughly subjective. Its importance in human economic, political, and social affairs has long been subsumed under the concept of *utility*—the recognition that societies must aspire to the greatest good (and the least suffering) for the greatest number. As Jeremy Bentham (1789, *Introduction to the Principles of Morals and Legislation*) famously said: "Utility is . . . that property in any object, whereby it tends to produce benefit, advantage, pleasure, good, or happiness . . . or . . . to prevent the happening of mischief, pain, evil, or unhappiness." Experienced affect is the neural currency for such cost-benefit "calculations" in the economy of the brain. When linked to specific perceptions, affective feelings typically signal the survival utility of objects.

There are, of course, an enormous number of affects, and it is by no means certain how any are instantiated within the brain. Although emotional feelings often appear related to objects of the world (since brains project feelings onto sensory/perceptual processes), affects are actually elaborated by specific brain systems. To the best of our knowledge, the critical systems are concentrated in ancient brain areas also found in many other animals.

Conceptually, affects may be divided into those that reflect bodily needs and disturbances—the hungers, thirst, and various other pains and pleasures of the world—while others are more closely related to instinctual actions—the expressive emotional urges of the mind. To understand the former, a guiding principle is that objects of the world that support survival are generally experienced as delightful and pleasant, while those incompatible with survival are experienced as aversive and unpleasant. The "sensory-linked affects" are typically studied as perceptual experiences of the brain; for instance, the taste of chocolate or the disgust engendered by the smell of feces. Such valenced experiences—the varieties of goodness and badness—are mediated by specific brain circuits that course upward through brain stem, thalamus, and hypothalamus to ancient limbic cortical areas of the brain. For instance, people with *insular* cortical damage are deficient in experiencing negative feelings such as pain, disgust, and coldness. Yet other cortical areas (e.g., orbitofrontal cortex) help distinguish many sensory pleasures.

The other major category of affective experience is more closely linked to emotional systems that allow organisms to generate adaptive instinctual behaviors during various life-challenging situations. Thus, all mammals have brain systems for: (1) seeking resources, (2) becoming angry if access to resources is thwarted, (3) becoming scared when one's bodily well-being is threatened, (4) various sexual desires that are somewhat different in males and females, (5) urges to exhibit loving and attentive care toward one's offspring, (6) feelings of panic and distress when one has lost contact with loved ones, and (7) the boisterous joyousness of rough-and-tumble playfulness. Each is manifested through characteristic action patterns that reflect the dynamics of the associated feelings. All other mammals may experience such basic feelings because of brain systems they share with humans. For instance, other mammals are attracted to the drugs that humans commonly overuse and abuse, and they dislike similar drug-induced experiences. Of course, there are many socially-derived feelings as various basic emotions are thwarted and blended in real life situations (yielding frustrations and feelings such as shame,

jealousy, guilt, or embarrassment, many of which may be uniquely human).

The vast human capacity to think and to symbolize experience in language and culture has added subtle layers of complexity to our feelings, especially our aesthetic experiences. As scientists categorize the diverse affective dimensions of life, many are tempted to simplify emotional complexities into holistic schemes (e.g., positive and negative affects) that may partly reflect our linguistic capacity to oversimplify. But there may also be superordinate brain systems for such global feelings.

Although humans have many special feelings ranging from awe to zoophobia, scientific understanding of the evolved nature of feelings is best obtained through the study of ancient brain systems we share with other animals. Recent evidence indicates these systems do have chemical codes, such as the neuropeptides, which help conduct specific neuroaffective tunes. Most of these substances, which barely cross blood–brain barriers, must be placed directly into animals' brains. However, as related medicinal agents are developed, we can anticipate the emergence of new and selective psychiatric drugs to control troublesome or excessive human feelings. For millennia, humankind had only one such drug, opium, which could alleviate physical pain as well as the painful grief arising from social loss.

So what, in a deep neural sense, are emotional feelings? They reflect the various types of neurodynamics that establish characteristic, mentally experienced "forces" that regulate and reflect action readiness within the nervous system—the pounding force of anger, the shivery feelings of fear, the caress of love, the urgent thrusting of sexuality, the painful pangs of grief, the exuberance of joy, and the persistent "nosy" poking about of organisms seeking resources. Moods and many psychiatric disorders may reflect the long-term balance or imbalance of the various positive and negative affective systems.

And how do the material events of the brain get converted into the mystery of subjective experience? No one is certain, but some have suggested that the core of our being is organized around neurosymbolic motor–action coordinates of the brain. The various basic neurodynamics of such a core "self," evident in the instinctual action dynamics of each animal, may be critical for the transformation of brain activities into emotional experiences. If this is the case, then certain affective values were built in at the very core of mammalian brain evolution, thereby providing a solid grounding for mental life. This view of brain–mind organization, not widely accepted by certain schools of materialist (e.g., behaviorist) thought, has the potential to contribute to a more accurate and admirable scientific image of life than was evident during the twentieth century.

AFFECTIVE DEVELOPMENT

Affect, as a feature or type of behavior, and hence a focus of psychology, is one of the least understood and most difficult problems in the field. *Affect* relates to or encompasses a wide range of concepts and phenomena, including feelings, emotions, moods, motivation, and certain drives and instincts. Anger, joy, fear, laughter, sadness, anxiety, pride, love, hate, and so on—all are so central to human experience, yet so little understood by psychology. Theorists and researchers have approached affect in numerous ways, often using idiosyncratic, contradictory, or mutually exclusive conceptualizations and operational definitions that have resulted in confusion and limited progress in our understanding of affect or any of these other related or synonymous constructs.

The psychology of *affective development* seeks to describe, map out, and explain the processes, continuities, and changes in the experience, differentiation, and expression of affect. Most often, affective development is placed in dichotomy, or even counterpoint, with cognitive development, reflecting an age-old concern with mind-body dualism (thinking vs. feeling). Much of the discussion centers around the primacy of one over the other or the nature of their interaction or mutual influence. Referents and resolutions are often sought in the social domain, whether in terms of social cognition or object relations, because of the complexity and salience of interpersonal and intrapersonal relations for ideas, attitudes, feelings, and behavior. Whatever categorizations may be hypothesized for the sake of theory building or empirical inquiry, it is important to bear in mind the complexity of affective development and the limited state of our current knowledge.

From its early days, psychoanalysis, as a clinical and developmental psychology, has centered on affective development. Psychologists influenced by the organismic developmental psychology proposed by Heinz Werner in 1940 have also had a long-standing interest in affective development. In the 1970s and 1980s a number of conceptual and methodological advances converged, bringing about a resurgence of interest, priority, and legitimacy for the study of affective development, and it remains a productive domain of inquiry as the twenty-first century unfolds.

Models of affective development vary in the degree to which they emphasize biological elements or socialization elements. Darwinian and ethological models are especially interested in unlearned complex behavior and often posit central nervous system specificity and correspondence between stimulus or elicitors and an individual's affective response. Socialization models emphasize learning processes, especially in the infant-caregiver interaction, and situational or environmental influences on affective experience or expression. Reliance on one or the other model type, of course, influences the manner in which affective development is understood or studied. For instance, biological re-

searchers might be more likely to measure electrophysiological responsiveness or neurophysiological correlates of specific emotions, whereas socialization researchers might be more interested in observing the quality of parent-child attachment and separation reactions over time. It is likely that multiple models and perspectives will be essential to furthering our understanding of affective development, and indeed such comprehensive and integrative approaches are evident in current theories of affective development such as Sroufe's organizational perspective and Tomkins's and Izard's differential emotions theory.

In his review of current knowledge on affective development, Yarrow states:

> Emotional expression can best be understood in a developmental context, in the framework of psychological changes accompanying the infant's increased autonomy, increasing awareness of a capacity to control people, objects, and self, and in the context of cognitive changes associated with a developing memory and the acquisition of object permanence. Similarly motor expression of emotion and the ability to inhibit and modulate responses to emotional stimuli are dependent on the maturation of the central nervous system. In examining the developmental course of emotional expression, it becomes evident that some aspects of emotional and cognitive development are on parallel lines; in other instances the cognitive skill is a prerequisite for emotional expression. Chronological age is not a simple variable; it is only a rough index of the psychological changes associated with the changing capacities of the child.

AFFERENT

Axons that are presynaptic to a neuron are commonly called *afferents.* In their terminal knobs is stored the neurotransmitter, which will be released into the synaptic cleft and which will bind to receptors on the postsynaptic dendrites and soma. Thus, the topic of afferents is extremely broad. Much information about afferent function has been obtained from the study of primary afferents.

Primary Afferents

The term *primary afferents* refers to the cells whose axons serve somatosensory receptors and that proceed to the central nervous system (CNS) through the dorsal roots of sensory nerve input to the spinal cord. The cell bodies of primary afferents are dorsal root ganglion cells located in the peripheral nervous system. The central axon synapses to postsynaptic cells at the segment level, at close segments, or at some distance from the entry point, even to the first synapse being in the brain stem at the dorsal column nuclei.

Primary afferents serve receptors for touch, thermal sensations, proprioceptive sensations from displacement of muscles and joints, and pain. Their sensory nerve classification is into groups I, II, III, and IV, on the basis of decreasing axonal diameter and decreasing conduction velocity. Most human physiology texts have a table showing these parameters, and most are currently incorrect (Peters & Brooke, 1998). This is because the data were obtained using feline nerves, which conduct much faster than human ones. A very rough rule of thumb is to halve the velocity and diameter to translate from cat to human. Human Ia fibers conduct in the approximate range of 40 to 60 meters per second.

Complexity of Primary Afferent Effects

Human physiology texts describe some of the common connections between primary afferents and motoneurons, serving the stretch reflex, the flexor withdrawal reflex, the inverse myotatic reflex, and so forth. What is not usually addressed is that these are simple paths surrounded by extremely complex additional projections of those afferents to other motoneurons and interneurons of the spinal cord (Baldissera, Hultborn, & Illert, 1981), and powerful modulating inputs onto those paths from spinal interneuronal pools (Jankowska, 1992; Pierrot-Deseilligny, Morin, Bergego, & Tankov, 1981; Brooke et al., 1997). It is clear that specific somatosensory receptor discharge can have widespread effects over neuronal pools of the spinal cord and brain and that the strength of the effect can be modulated from profound to minimal (Brooke et al., 1997).

Regulatory Effects of Primary Afferents in Motor Control

Primary afferents play a significant role in motor control (Pearson, 1993). In locomotion, primary afferents transmit sensory information on load bearing, muscle stretch, joint position, and cutaneous sensations and are involved in such matters as the transition from stance to swing or from static to dynamic balance in the initiation of stepping. Their reflex effects, ipsi- and contralaterally through Ia and cutaneous afferent activation, in the human are substantially modulated over cycles of activities such as walking (Brooke et al., 1997). In addition to spinal paths from sensory receptors to motoneurons and motor interneurons, it is clear that primary afferent activity regulates the activity of other primary afferents in complex and organized ways (Rudomin, Romo, & Mendell, 1998). Often, this involves presynaptic inhibition (Stein, 1995). Such sensorisensory

conditioning is seen across much of the animal kingdom (Watson, 1992).

Gain Control in Human Primary Afferent Transmission Over Spinal Paths

In humans, Ia transmission monosynaptically to leg motoneurons—for example, the Hoffmann (H) reflex—is attenuated by muscle spindle activation of Ia afferents serving uniarticular extensor muscles of the hip or knee or, probably, ankle. The inhibitory pathway is, at least in part, spinal through presynaptic inhibitory interneurons (Brooke et al., 1997). Such centripetal sensorisensory conditioning is complemented by centrifugal conditioning arising from the brain and from central pattern-generating networks of the spinal cord and brain stem (Rudomin et al., 1998). For example, immediately before voluntary plantar flexion movement, H-reflex magnitudes in the plantar flexor muscle soleus increase considerably.

There seems to be clear separation of the control of Ia afferents and cutaneous afferents during locomotion. Locomotor-induced modulation of cutaneous afferent affects on motoneurons appears to arise from centrifugal conditioning but, unlike the Ia pathways previously described, not as attenuation from centripetal conditioning from somatosensory afferents activated as a consequence of the movement per se (Brooke, McIlroy, Staines, Angerilli, & Peritore, 1999).

Primary afferent activation can also reveal novel membrane characteristics of motoneurons. A brief burst of Ia afferent firing can reset membrane currents so that plateau potentials occur in mammalian motoneurons (e.g., in stance), being a rapid series of action potentials from a depolarized plateau (Kiehn, 1991). Such repetitive motoneuronal firing, continuing well beyond the duration of the Ia afferent burst, can then be terminated by a brief burst of firing of high threshold primary afferents.

Gain Control in Human Primary Afferent Transmission Over Ascending Paths

Excitation of primary afferents in peripheral nerves at low stimulus intensities rapidly results (from arms, in 15+ ms; from legs, in 25+ ms) in somatosensory evoked potentials (SEPs) measured from scalp electrodes recording from the somatosensory reception areas of the cerebral cortex. As previously described for spinal Ia reflexes, the ascending path from fast-conducting afferents to the brain can be attenuated at spinal levels by activation of other Ia afferents (Staines, Brooke, Misiaszek, & McIlroy, 1997). The effect is observed as reduced magnitudes of SEPs, despite nonvarying stimulation. Further, just as the brain can centrifugally control primary afferent transmission in Ia spinal reflexes, so it can also control the transmission through the ascending path (Rudomin et al., 1998). For example, SEPs are attenuated following learning that involves those pathways online (Nelson, Brooke, McIlroy, Bishop, & Norrie, 2001).

The attenuation reduces SEP magnitudes by as much as 50% of initial control values. Accompanying behavioral evidence of failure to use the pathways in predictable conditions suggests that the brain control of transmission from the primary afferents is linked to a switch from reactive to predictive control using an internal model (Nelson, 1996). Such a switch probably reflects a difference in brain sites involved in the motor control for the tasks. Thus, stimulation of primary afferents and observation of subsequent neural response shed light on the neural organization for skilled behavior.

AFFILIATION NEED

Need for affiliation (*n Aff*) was 1 of 20 psychological needs identified by H. A. Murray and measured through his Thematic Apperception Test (TAT). The *n Aff* is scored when one or more of the characters in a subject's TAT story shows concern "over *establishing, maintaining, or restoring a positive affective relationship with another person*" (italics in the original). Individuals scoring high on *n Aff* on Gough's Adjective Check List tend to describe themselves in such terms as friendly, warm, trusting, talkative, cheerful, kind, loyal, helpful, praising, accepting, and generous. These characteristics are more likely to be associated with feminine than with masculine personality stereotypes. S. Miller and K. M. Nardini found, for example, that women scored higher than men on a measure of affiliation tendency, while Bose, Das Gupta, and Lindgren observed that female undergraduates in Calcutta who took a Bengali test measuring *n Aff* and need for achievement (*n Ach*) scored higher on *n Aff* and lower on *n Ach* than male undergraduates did.

There is considerable evidence to show that *n Ach* and *n Aff* are negatively correlated, probably because the two motives are generally expressed in mutually incompatible forms of behavior.

Studies generally confirm hypotheses based on *n Aff* theory. Lansing and Heyns, for instance, found that *n Aff* was significantly related to frequency of local telephone calls made by subjects, although it was only weakly related to numbers of letters written or frequency of visits to relatives and close friends living at a distance. Sid and Lindgren found that women students majoring in nursing and education rated higher on a measure of *n Aff* than did students in other major fields, and that the *n Aff* of expectant mothers was higher than that of any other group tested.

The possibility that affiliation tendency is characterized by sensitivity to rejection was explored by Mehrabian, who found the two traits to be essentially unrelated. Both variables were negatively correlated with a measure of achieving tendency, but affiliation tendency was positively correlated with measures of empathy and arousal-seeking tendency, whereas sensitivity to rejection was negatively correlated with arousal-seeking tendency and social desirability. Mehrabian found, however, that scores on measures of affiliative tendency and sensitivity to rejection could be combined to produce a single measure of dependency.

AGE DIFFERENCES

Behavioral changes with age are as striking as changes in physical appearance. Both training and altered structures contribute to these psychological differences. Differences that occur throughout the life span are mainly studied by *cross-sectional* and *longitudinal* methods.

Age differences in intelligence have been extensively studied. Mental age (MA) as measured by standard intelligence tests increases with chronological age (CA), and because of the way age scales are constructed, the relation is linear. An average child shows an increase of 1 year in MA for each year of CA until about 15 to 18 years of age, when MA is assumed to level off. There is evidence, however, that the intellectual ability of some individuals may continue to increase at least until they are in their early 20s.

The question of the growth of MA with age is complicated by two factors: (1) the difficulty level of items for young adults, and (2) the different composition of abilities tested at different age levels. If there are few difficult items at the upper end of the scale, older subjects cannot show improvement: The ceiling of the test is too low. If the same functions are not being tested at different age levels, what does it mean to say that MA *increases* with age?

The constancy of IQ across time has long been an age-related issue. In general, IQs of schoolchildren and adults have been found to be constant enough to allow satisfactory prediction over several years. And within limits, the older the subjects, the longer the test scores remain relatively constant (within 4 to 5 IQ points). At the opposite extreme, preschool IQs are very poor predictors of scores obtained later in life. It should be emphasized, however, that, even when test-retest correlations are high for a group, sizable systematic shifts in IQ can occur in particular individuals. A change of 30 or more points in a mean of 12 years has been found in 9% of the cases studied by Honzik, Macfarlane, and Allen.

Interestingly, there is often a large drop in IQ a few years before death, regardless of when death occurs. Such a drop in IQ can even be used to predict death.

The fact that recognition memory and recall show decided improvement in children, say, between ages 6 and 9 is probably related to an increase in mental age. The older children use implicit verbalization more—labeling, rehearsing, and comparing stimuli. Age seems to affect recall performance more than recognition, improving performance in children and hindering it in old age.

A fair number of generalizations can be made about behavior changes in later life.

1. Since behavior is in part a product of the central nervous system, the loss of brain cells with age is probably a relevant consideration. By the age of 80 or 90, 40% of cortical cells may be lost. Also, water content declines and fats increase in the brain over the life span.
2. Older people definitely have more health problems than the young, which inevitably modifies their behavior.
3. Visual acuity and accommodation decline because of the increase in opacity and loss of elasticity of the lens of the eye in middle age. Changes in the retina later in life also impair color vision and increase sensitivity to glare.
4. Similarly, in audition, perception of higher frequencies disappears in the middle years, and after age 65 many adults require (although they do not necessarily use) hearing aids. Stress due to hearing loss can produce depression and other emotional disorders.
5. There is also declining sensitivity in taste, smell, and pain in the later years.
6. Older people seem to take longer to learn verbal material than do the young. However, when the learning of older people is self-paced and meaningful, they perform well. They also improve in learning and long-term memory when instructed to use mediating or mnemonic devices.
7. Older people's deficit in long-term memory seems to be mainly one of retrieval; short-term memory is impaired only when the task requires divided attention (e.g., dichotic listening). Span remains essentially intact until very advanced years.
8. Individual variability in all intellectual tasks increases over the life span, but this does not pose an educational problem until around 70 years of age or later.
9. With increasing age the central nervous system slows down. This change appears to account for the gradual decrease in speed of responding across the life span for a wide range of tasks, including reaction time, sorting objects, copying, canceling, and other similar processing functions.
10. Although there are few studies on problem solving and creativity as functions of aging, some hypotheses have emerged:
    - Older subjects tend to ask uninformative questions, to be disrupted by irrelevant and redundant information, and to treat both positive and negative instances of a concept as positive. Failure to profit from negative information can make a person seem rigid.
    - If memory load is kept low and older people are given strategy hints and the like, age-related deficits in problem solving can be substantially reduced (Sanders et al., 1975).
    - Although Lehman (1953) concluded that most creative achievements occur early in a scientist's or artist's career, considerable evidence indicates that some of the most valuable contributions come late in life. For example, Claude Monet began his famed "Water Lily" series at age 73; Benjamin Franklin invented the bifocal lens at 78; Sophocles wrote *Oedipus Rex* at 75; and George Bernard Shaw wrote his first play at 48. When the quality of works by Bach and Beethoven is assessed by the number of times a piece has been recorded, the latest works excel.
11. As one grows older, interests change; for example, the participant in sports becomes a spectator, and the incidence of crime declines steadily.
12. Finally, well-conducted sequential studies suggest that a person's personality is characterized more by continuity than by change. Cohort differences appear to be more prevalent than age changes.

AGING AND INTELLIGENCE

Phenomena of aging effects on intellectual and cognitive functioning are investigated by research approaches at the psychometric, information-processing, and biological levels. These approaches complement each other and should be considered conjointly for a comprehensive overview of aging and intelligence. Recent neurocomputational approaches help to integrate theory and data across these levels.

The Behavioral Psychometric Approach

Extant psychometric data on aging and intelligence indicate three major phenomena. First, intellectual aging is multifaceted. Multifactorial models of intelligence (e.g., the *Gf-Gc* theory; Cattell, 1971; Horn, 1982; the dual-process model of life span intellectual development, Baltes, Staudinger, & Lindenberger, 1999) suggest that abilities in the *fluid-mechanics* (*Gf*) domain, which reflect an individual's capacity for problem solving, information organization, and concentration, are more biology based. In contrast, abilities in the *crystallized-pragmatic* (*Gc*) domain reflect the acquisition and use of culture-based information.

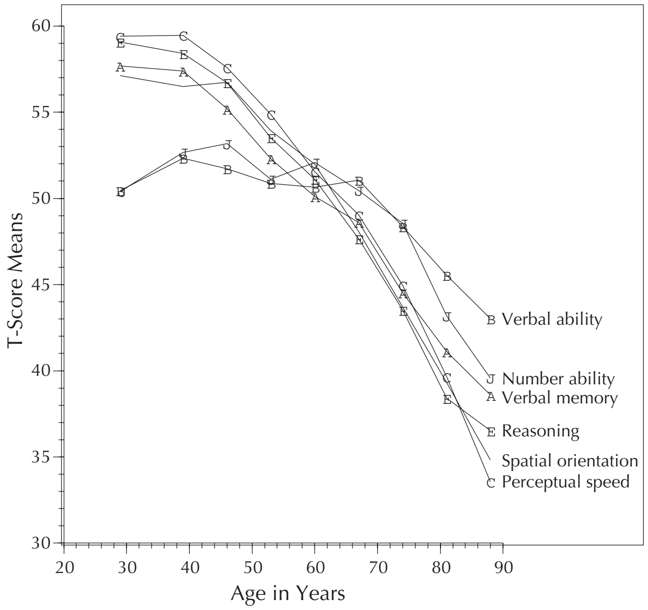

Figure 1. Cross-sectional age gradients in six primary mental abilities (N = 1,628). Abilities were assessed with three to four different tests and are scaled in a T-score metric.

Source: Data based on Schaie & Willis (1993); figure adapted from Lindenberger & Baltes (1994).

Figure 1 shows that cross-sectional age gradients of primary mental abilities (Thurstone & Thurstone, 1949) in the fluid-mechanics domain (i.e., verbal memory, reasoning, spatial orientation, and perceptual speed) decline linearly beginning in the 40s. However, abilities in the crystallized-pragmatic domain (i.e., verbal and numeric abilities) remain stable up to the 60s or 70s (Schaie & Willis, 1993).

Second, cross-sectional age differences are generally more pronounced than longitudinal age changes. Whereas modest *cross-sectional negative age differences* are found by the 40s for some abilities and by the 60s for most abilities, moderate *longitudinal negative age changes* in most abilities are usually not evident until the mid-70s or early 80s (Hayslip, 1994; Schaie, 1983, 1996). Discrepancies between cross-sectional and longitudinal age gradients are due to cohort effects (Schaie, 1965), practice effects, and selective attrition in longitudinal studies (Lindenberger & Baltes, 1994). After controlling for cohort and historical time effects, discrepancies between cross-sectional age differences and longitudinal age changes are reduced (Schaie, 1996). In addition, studies extending to very old age have provided opportunities for observing age differences and age changes in the 90s and beyond (e.g., the Berlin Aging Study, Baltes & Mayer, 1998; the Georgia Centenarian Study, Poon, Sweaney, Clayton, & Merriam, 1992; and the Kungsholmen Project, Small & Bäckman, 1997).

Third, aging contracts the factor space of intellectual abilities. Ample cross-sectional data show that correlations among subscales are generally larger in older samples, indicating an increasing degree of ability dedifferentiation (e.g., Babcock, Laguna, & Roesch, 1997; Balinsky, 1941; Baltes, Cornelius, Spiro, Nesselroade, & Willis, 1980; Lindenberger & Baltes, 1997; Lienert & Crott, 1964). Similar patterns have also been found in longitudinal studies, although the trends of dedifferentiation are not as strong as in the cross-sectional findings (McHugh & Owens, 1954; Schaie et al., 1998). Furthermore, ability dedifferentiation generalizes beyond the intellectual domain. A series of recent studies using simple measures of sensory acuity (Baltes & Lindenberger, 1997; Lindenberger & Baltes, 1994; Salthouse, Hancock, Meinz, & Hambrick, 1996), contrast sensitivity, and muscle strength (Anstey, Lord, & Williams, 1997) report an increase in the sensory-cognitive correlation with advancing age in age-heterogeneous samples. The strengthening of the sensory-cognitive link in old age has been interpreted as an indication of general neurological decline affecting both domains of functioning (e.g., Baltes & Lindenberger, 1997). The nature of the sensory-cognitive link is, however, still under debate. A few recent studies took the experimental, instead of the correlational, methodology to study the sensory-cognitive link. Findings from these studies suggest that as people grow older they seem to allocate an increasing amount of resources to tasks that require maintaining balance in an upright posture or walking (e.g., Lindenberger, Marsiske, & Baltes, 2000; K. Z. H. Li, Lindenberger, Freund, & Baltes, 2001).

The Behavioral Information-Processing Approach

In formulating theories of intelligence, researchers have examined several information-processing mechanisms or resources that may mediate age-related differences in intelligence. A common hypothesis of cognitive aging is that aging constrains general cognitive resources (GCRs). Three related types of GCRs—working memory, processing speed, and inhibitory mechanisms—have been investigated most extensively in relation to the fluid-mechanics domain of intelligence.

Working Memory

Working memory (WM) refers to the ability to simultaneously hold information in immediate memory while transforming the same or other information (Baddeley, 1986). Associated with higher-level cognition, WM is involved in language processing, problem solving, and concurrent task performance. Age-related declines in WM performance have been well documented (Craik & Jennings, 1992; Zacks, Hasher, & Li, 2000). Furthermore, large-scale studies show that a substantial portion of age-related variance in *Gf* abilities is shared with age-related differences in WM (e.g., Salthouse, 1991).

Processing Speed

In this view, age-related intellectual declines have biological underpinnings, such as neuronal slowing, which lead to

the slowing of basic cognitive operations and exacerbated effects in complex tasks (Birren, 1964; Cerella, 1990; Jensen, 1993). Correlational analyses show that the observed age-associated variance in *Gf* abilities is greatly reduced or eliminated after individual differences in processing speed are controlled for (e.g., Park et al., 1996; Salthouse, 1996).

Attention and Inhibitory Mechanisms

It has also been proposed that aging impairs attention and inhibitory processes, leading to greater interference and difficulty in suppressing previously relevant information and habitual responses, as measured using tasks such as Stroop color naming, negative priming, and response stopping (e.g., Hasher & Zacks, 1988; Hasher, Zacks, & May, 2000). Measures of interference proneness have accounted for significant proportions of age-related variance in cognitive performance (e.g., Salthouse & Meinz, 1995), although fewer efforts have been made to link intelligence tests to measures of inhibition in comparison to the processing speed literature. Nonetheless, strong theoretical and empirical links appear to exist among all three GCRs, which may be best conceptualized as basic mechanisms (speed, inhibition) nested within more complex cognitive functions (WM).

The Cognitive and Computational Neuroscience Approaches

Recent developments in cognitive neuroscience have motivated researchers to investigate functional relationships between aging deficits in basic cognitive mechanisms and their biological underpinnings (Figure 2). The biological correlates of aging effects on intelligence examined so far involve molecular and neuronal mechanisms.

Molecular Correlates

ApoE is a plasma protein involved in cholesterol transportation. There is recent consensus that the ε_4 variant of ApoE is a risk factor for developing Alzheimer's disease. It may also relate to milder forms of nonclinical cognitive impairment (see Small, Basun, & Bäckman, 1998, for reviews).

Neuronal Correlates

Besides anatomical changes (Raz, 2000), there is consensus that during the course of normal aging the concentration of neurotransmitters—for instance, dopamine—in the frontal cortex, striatum, and basal ganglia decreases by 5–10% in each decade of life (e.g., Kaasinen et al., 2000). Functional relationships between aging-related deficits in the dopaminergic system and age-related decrements in various aspects of information processing have also been documented. For instance, the density of dopamine receptors in the nigrostriatum associates negatively with reaction time (RT)

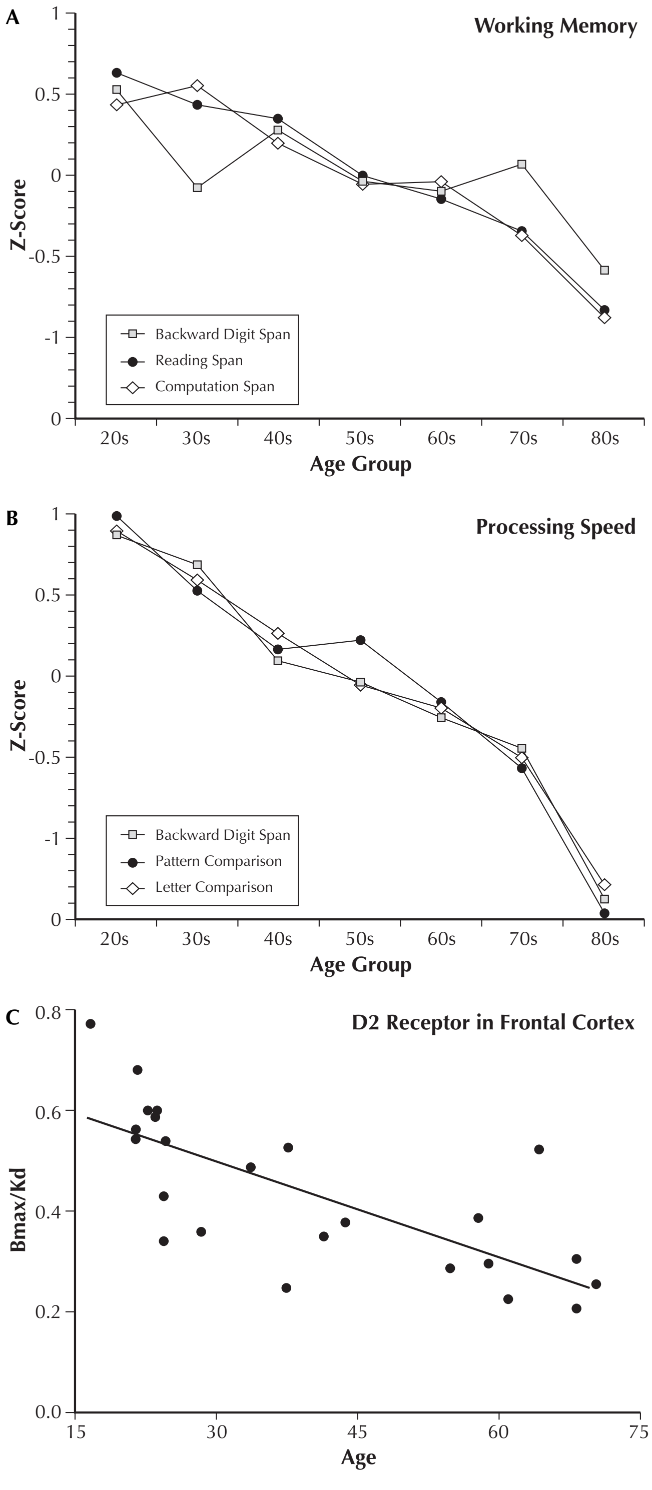

Figure 2. Aging-related declines in information processing and neurotransmitter density.
Negative adult age differences in working memory (A), processing speed (B), and dopamine D2-like receptor availability in the frontal cortex (C).

and positively with RT variance (Spirduso, Mayfield, Grant, & Schallert, 1989). Other studies have demonstrated that WM function is reduced in aged monkeys due to attenuated dopaminergic function (for review see Arnsten, 1998).

Recent *neurocomputational approaches* provide computational explications for linking aging-related decline in neuromodulation and cognitive deficits. For instance, simulations show that declines in dopaminergic modulation could be related to reduced neural information-processing fidelity, cortical representation distinctiveness, and various aspects of cognitive aging deficits (S.-C. Li, Lindenberger, & Sikström, 2001). Other models relate deficits in dopamine modulation more specifically to aging effects on memory context representation and maintenance (Braver et al., 2001) and on error processing (Nieuwenhuis et al., 2002).

Conclusions

Psychometric studies conducted since the 1920s indicate that intellectual aging is not a unitary process. Culture-based intelligence is maintained into the 70s, whereas biology-based intellectual abilities begin declining in the 40s. There is growing interest in understanding cognitive and neurobiological mechanisms that may underlie age-related declines in *Gf* abilities. At the information-processing level, factors such as WM, processing speed, and inhibition mechanisms are correlated with age differences in intelligence. Furthermore, there is emerging consensus that the prefrontal cortex and its supporting neuromodulation mechanisms underlie such cognitive functions. At present, the cross-level link from brain aging to intellectual aging continues to be refined.

AGRAPHIA

Definition

Agraphia (dysgraphia) is a systematic disorder of written language due to cerebral disease (Benson & Cummings, 1985; Bub & Chertkow, 1988; Hinkin & Cummings, 1996). It denotes a disturbance of writing in various physical forms; spatial or apraxic disorders may also contribute. It is not contingent on motor or sensory impairment, although combinations occur. Callosal lesions may cause unilateral agraphia (Roeltgen, 1993, 1997). Accompanying aphasia, agraphia usually reflects its pattern and severity; it is considered part of the supramodal language deficit (Kaplan, Gallagher, & Glosser, 1998; Ulatowska, Baker, & Stern, 1979).

Occurrence

Agraphia rarely coexists with alexia or occurs in isolation. Its hallmarks are paragraphias, on either a letter (literal) or word (verbal or semantic) level. Additionally, automatisms, perseverations, and syntactic or word-finding difficulties may occur as with spoken language.

Model of Writing

The model of a central language system comprises three components: phonology (speech sound production), lexicon (vocabulary), and syntax (sentence construction). Within the secondary language system of writing, an additional phoneme-to-grapheme conversion system is necessary, triggering the motor patterns for letters and an orthographic system.

While strings of letters are generated via the phonological route, entire words are produced via the semantic route. Various readers may rely more or less on one or the other, but usually they work in parallel fashion (the dual-

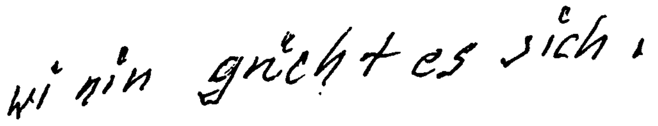

Figure 1. Handwriting of a 66-year-old right-handed man who had suffered a left temporal cerebral hematoma one month previously, developing transcortical-sensory aphasia. On dictation ("Wohin wird sie es mir bringen?" [Where is she going to take it for me?]) he wrote: "wi nin gricht es sich," producing literal (first three words) and verbal (last word) paragraphias.

route hypothesis). They may, however, be impaired selectively, yielding to different agraphia types.

Clinical Examination

Examination for agraphia includes spontaneous writing, writing to dictation (Figure 1), and written naming. If the dominant arm is paralyzed, writing may be attempted with the nondominant arm. A distinction between linguistic and spatial components of agraphia is best made by copying. To compensate for impaired motor abilities, letter or word synthesis using printed material may be used. Testing for kinesthetic reading, letter synthesis using sticks (matches), oral spelling, and reading may also be helpful.

Clinical Varieties

Pure Agraphia

This consists of severe inability to write without gross aphasia or alexia, leading to scribbling or misspelling. Production of single words in a barely legible fashion may be possible. Lesions are found in the left parieto-occipital region or second frontal gyrus (Exner's center). The distinction between pure and apraxic agraphia is questioned by some authors (Kaplan et al., 1998).

Aphasic Agraphia

This is part of aphasia, whose type and severity it reflects. Therefore, screening for agraphia may be used in testing for aphasia. Lesions are located in the classical language zones (i.e., in the distribution of the middle cerebral artery; Figure 2).

Neurolinguistically, three types may be defined. *Lexical agraphia* consists of a disability to convert phonemes to graphemes, especially with irregular spelling, resulting in phonetic writing without lexical control. Lesion sites are the posterior superior parietal lobule and the angular gyrus. *Phonologic agraphia* consists of holistic writing of words with occasional failure to produce entire words that cannot be written in a letter-by-letter fashion. The patient fails in dictated pronounceable nonsense words while succeeding in well-known imageable words. Lesions are in the

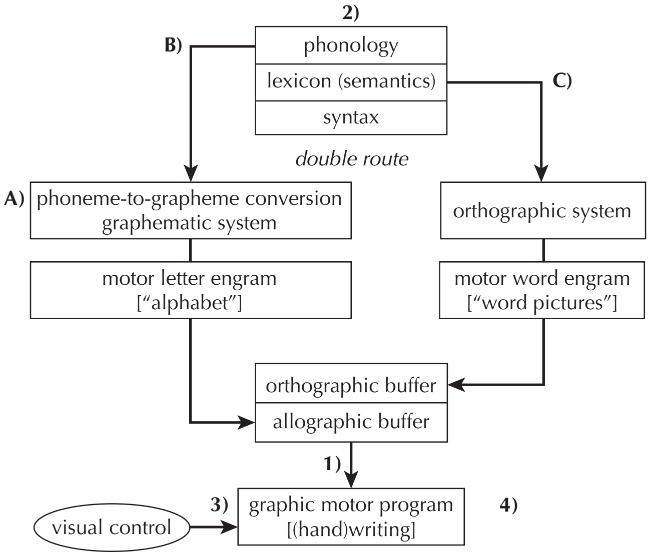

Figure 2. Proposed neurolinguistic model of writing. The letters and numbers indicate the presumed sites of disruption.

anterior inferior supramarginal gyrus or the adjoining insula. Patients with *semantic agraphia* may successfully write real and nonsense words to dictation but have difficulties in written confrontation naming or description.

In analogy to deep and surface alexia, deep and surface agraphia have been distinguished. *Deep agraphia* is characterized by semantic paragraphias (e.g., *airplane* for *propeller;* Roeltgen, 1997), whereas in *surface agraphia* mostly literal paragraphias are produced (e.g., *propettle* for *propeller*). In languages with irregular orthography such as English, surface agraphia seems to be more frequent than in languages with regular orthography.

Spatial Agraphia

Letters or words are incorrectly placed, closed in, omitted, of quite unequal shape and size, or augmented by superfluous strokes. In *neglect agraphia* words or letters at the margin of a page are omitted, or the lines show a marked slope toward one side. Patients often suffer from right parietal brain injury presenting with spatial deficits in nonlanguage tasks.

Apraxic Agraphia

Single letters are malformed or confused according to their graphic (e.g., M and W) rather than their phonetic similarity. This variety is consequent to the loss of graphic motor programs necessary for writing. Apraxic agraphia resembling pure agraphia has been described in terms of a modality-specific apraxia, but (ideomotor) apraxia is usually present in nonlanguage tasks. In Gerstmann's syndrome, elements of aphasic, spatial, and apraxic agraphia mingle. Lesions are found in the left parietal lobe, especially near the angular and supramarginal gyri.

AGRICULTURAL PSYCHOLOGY

In contrast to other social sciences that have developed specialized applications to agriculture, psychology is not known for its concern with rural issues. For instance, there are no psychological counterparts to specialties such as agricultural economics, rural sociology, agricultural marketing, or rural geography. Nonetheless, psychological perspectives have interacted with agriculture in several domains: (1) assessment of therapeutic needs of rural populations, (2) investigation of farming tasks and skills, (3) analysis of expert agricultural judges, (4) evaluation of farming decisions, and (5) statistics and experimental design.

Therapeutic Needs

Rural life is often portrayed as idyllic and down-to-earth. Rural communities are assumed to be less stressful and more humane. However, epidemiological studies reveal serious mental health problems in rural settings. In fact, many psychopathologies have higher rates of incidence in agricultural areas. Despite their need, rural communities often lack mental health services taken for granted in cities.

One major reason for the lack of mental health services is that most therapists are trained in urban universities. Faculty (and students) are unfamiliar with the values, concerns, and language of rural living. Consequently, specialized programs and methods (e.g., traveling clinics and in-school programs) are necessary to prepare mental health care providers with the strategies they need to cope with problems encountered in rural communities.

One issue receiving attention in rural communities is child abuse. Rural environments are different in many respects from urban environments, which are more widely understood. It should not be surprising, therefore, to find that rural child abuse is perceived differently and frequently goes unreported. Nonetheless, home-based early intervention programs are successful in helping at-risk children.

Farming Tasks and Skills

Traditionally, farmers and ranchers were expected to be skilled in many manual and physical tasks. Work psychologists found that dairy workers are proficient in nine separate tasks, ranging from operating milking machines to evaluating the health of cows. Thus, a traditional farmer needed to be a jack of all trades, with general skills in many areas.

However, with increased mechanization and computerization in agriculture, there is a shift. Instead of many general abilities, fewer specialized skills are necessary now. Instead of emphasizing manual skills, modern agribusiness places greater demand on cognitive abilities: For example, a combine harvester involves simultaneous control of at least seven tasks. Given this complexity, the high rate of farm accidents may be due, in part, to overstressed human factors components.

With the trend away from small family farms to large corporate farming, there is also a greater need for farmers with sophisticated problem-solving and management skills. This has produced changes in both the education and the practice of farmers. As a result, behavioral investigators turned their interests toward analysis of higher thought processes.

Agricultural Expertise

Initial insights into the psychology of expertise arose from studies of agricultural workers. For instance, H. D. Hughes conducted one of the earliest studies of experts in 1917. He found that corn rated highest by expert corn judges did not produce the highest yield. Henry Wallace (later vice president under Franklin D. Roosevelt) reanalyzed Hughes's data using path analysis. He showed that (1) corn judges largely agreed with each other, but (2) their ratings correlated only slightly with crop yields.

In similar research, licensed grain inspectors were found to misgrade nearly one third of wheat samples and, when grading a second time, gave over one third a different grade. Also, increased experience made judges more confident but did not necessarily increase accuracy. Finally, more experi-

enced judges tended to overgrade wheat samples (perhaps the original "grade inflation").

One source of errors in agricultural judgment is the presence of irrelevant factors. Gary Gaeth and James Shanteau found that nondiagnostic material (e.g., excessive moisture) had a significant impact on decisions by soil judges. However, cognitive training successfully compensated for these irrelevant materials. Another approach to improving expert judgment was used in weather forecasting: Precipitation forecasts were improved using Brier scores (a quadratic scoring system). Recently, accuracy of short-term weather forecasts has increased dramatically.

Farm Management Decisions

There have been analyses of the choices needed to manage a farm. Most of this work is concerned with how economic decisions should be made. Various methods have been proposed to help farmers choose more effectively. For instance, farmers often make suboptimal allocations when buying crop insurance. However, farmers can be persuaded to make more effective decisions by taking a longer time perspective.

Insights into marketing and consumer behavior have arisen from studies in agriculture. For instance, the pioneering analysis of new-product diffusion by Everett Rogers in 1962 was based on farmers' willingness to adopt new agricultural equipment. His classification of consumers into "innovators, early adopters, early majority, late majority, and laggards" is now widely accepted.

Statistics and Experimental Design

One area with a long-standing interface between psychology and agriculture is statistical analysis and design. A century ago, psychologists such as Francis Galton were instrumental in developing modern statistical thinking. Later psychologists (e.g., James McKeen Cattell and L. L. Thurstone) extended the application of statistics in behavioral research.

Statisticians working in agriculture (such as R. A. Fisher) developed much of what is now standard experimental design and analysis. For instance, random assignment and factorial designs were initially originally devised for agricultural science. Many terms used in statistics—for example, *split-plot designs*—reflect this agricultural origin.

In summary, although agricultural psychology is not normally recognized as a subfield of psychology, there have been many applications of psychology in agriculture. Moreover, agricultural issues have affected psychology in many often unappreciated ways.

AKATHISIA

The term *akathisia* (literally, "not to sit") was introduced by the Bohemian neuropsychiatrist Lad Haskovec in 1901 (Haskovec, 1901). Akathisia represents a complex psychomotor syndrome that consists of a subjective (emotional) and an objective (motor) component (Brüne & Bräunig,

Table 1. Subjective Symptoms of Akathisia

- Inner restlessness
- Urge to move (tasikinesia)
- Inability to remain still
- General unease
- Discomfort
- Inability to relax
- Poor concentration
- Dysphoria
- Anxiety
- Fear
- Terror, rage
- Suicidal ideation
- Aggressive thoughts

Table 2. Objective Symptoms of Akathisia

Sitting Position	Standing Position
Fidgetiness of arms and hands	Marching on the spot
Rubbing face	Changing stance
Rubbing, caressing, or shaking arms or hands	Flexing and extending knees
	Rocking from foot to foot
Rubbing or massaging legs	Pacing, walking repetitively
Tapping, picking on clothes	
Crossing and uncrossing arms	
Crossing and uncrossing legs	
Swinging or kicking crossed legs	
Tapping toes	
Frequently squirming in chair, making straightening motions	
Rocking and twisting the body	

Table 3. Differential Diagnosis of Akathisia

Subjective Component Prominent	Objective Component Prominent
Psychotic agitation	Restless-legs syndrome
Anxiety	Tardive dyskinesia
Agitation due to affective disorder	Stereotypies
	Tremor
Drug withdrawal syndromes	Myoclonus
Neuroleptic dysphoria	Restless, repetitive movements due to organic disorder (e.g., pacing in dementia, hyperactivity in Tourette's syndrome)
Agitation due to organic disorder (e.g., dementia, hypoglycemia)	

1997; Sachdev, 1995; see Tables 1 and 2). Subjectively distressing inner restlessness and repetitive movements of the legs are the most frequent symptoms, predominantly emerging when the patient is in a standing or sitting position, with some relief taking place when the patient is lying. However, none of the symptoms is pathognomonic, making it difficult to distinguish akathisia from other forms of restlessness as well as from other movement disorders (Sachdev, 1994, 1995; see Table 3).

Although probably first mentioned in postencephalitic parkinsonism and in idiopathic Parkinson's disease long before neuroleptics became available, akathisia is nowadays mostly associated with the administration of antipsychotic drugs. "Classical" antipsychotics with a high affinity to dopamine D2 receptors are much more likely to produce akathisia than are atypical antipsychotics. However, agents targeting serotonin receptors are also suspected of causing an akathisialike syndrome. Akathisia is of specific clinical relevance because it may complicate the treatment by inducing noncompliant and impulsive behaviors, which may include assaultive and suicidal actions (Van Putten, 1975). Moreover, akathisia is sometimes mistaken as psychotic agitation or even overlooked (Van Putten, 1975; Weiden, Mann, Haas, Mattson, & Frances, 1987). Since the 1980s, several clinically useful rating scales for akathisia have been published to improve systematic evaluation (details in Brüne & Bräunig, 1997; Sachdev, 1995).

Akathisia generally has an acute beginning within hours or days after initiation of antipsychotic treatment. High initial dosages and rapid dose increment are predisposing factors to produce acute akathisia (Sachdev & Kruk, 1994). Other subtypes of akathisia have been described according to the time of onset during antipsychotic treatment with more ambiguous risk factors (see Table 4). When a patient is taking a chronic course, subjective distress may decrease and the movement patterns look more like stereotypies, suggesting an overlap with tardive dyskinesia (Barnes & Braude, 1985).

The reported prevalence and incidence rates vary considerably, depending on the applied diagnostic criteria (Brüne & Bräunig, 1997; Sachdev, 1995; Van Putten, May, & Marder, 1984).

Table 4. Subtypes of Drug-Induced Akathisia

Subtype	Description
Acute akathisia	Onset within 6 weeks of initiation of treatment, dose increment, or change of drug type; concurrent medication not decreased or discontinued
Chronic akathisia	Symptoms persist for over 3 months; specify acute, tardive, or withdrawal onset
Tardive akathisia	Onset at least 3 months after initiation of treatment, dose increment, or change of drug type; no dose increment or change of drug within 6 weeks prior to onset; concurrent medication not decreased or discontinued
Withdrawal akathisia	Onset within 6 weeks of discontinuation or marked reduction of dose; prior to onset, duration of treatment at least 3 months; concurrent medication not decreased or discontinued
Pseudoakathisia	Typical objective symptoms without subjective distress

Source: Modified from Sachdev (1994).

The pathophysiology of akathisia is far from being fully understood. Akathisia may best be viewed as resulting from the interaction of dopaminergic neurones with noradrenergic, serotonergic, cholinergic, GABAergic, glutamatergic, and opioid systems in mesolimbic and mesocortical pathways (Sachdev, 1995).

Early diagnosis is critical due not only to the possible complications associated with akathisia but also to the impending dilemma of insufficient or delayed treatment response. Thus, preventive measures, such as choosing the lowest effective dose and employing the stepwise increment of dose, are indispensable (Sachdev, 1995). Moreover, routine clinical checks for extrapyramidal side effects and behavioral observation (e.g., during occupational therapy or other group therapies) are recommended (Brüne & Bräunig, 1997).

If akathisia is present, stopping the offending drug or at least reducing the dose is considered to be the best option (Sachdev, 1995). However, in highly agitated patients, waiting for a spontaneous wearing-off may be impracticable. Anticholinergic drugs, receptor antagonists, and benzodiazepines are effective for acute treatment, yet response rates are variable. If onset of akathisia is less acute, a change of antipsychotic class or administration of modern agents is proposed. Treating chronic or tardive akathisia is probably less effective (Brüne & Bräunig, 1997; Sachdev, 1995).

ALEXIA/DYSLEXIA

In an increasingly literate world, the inability to read becomes a significant disability that may affect academic success, employment, and self-concept. Because widespread literacy is a recent historical development, it should not be surprising that it was only about 100 years ago that the first case of alexia or "word blindness" was described. By definition, the term *alexia* describes a condition where reading ability is lost as the result of some neurological insult, such as head injury or stroke. With alexia, it is assumed that the individual had adequate reading achievement prior to the neurological insult.

The clinical and experimental literature on alexia has greatly increased understanding of dyslexia. The term *dyslexia* refers to an inborn or congenital inability to learn to read. The term rose out of the medical literature and is not completely accepted by many educators who work with children with reading difficulties. Many educators and psychologists prefer the terms *developmental reading disorder* or *reading disability,* because they avoid the implication that the etiology of the reading disorder is due to neurological deficits. Consequently, the term *dyslexia* is most appropriate when it describes a severe reading disability presumed to be neurologic in origin. Although prevalence estimates vary, the incidence of dyslexia has been estimated at 3% to 8% of the school-aged population. Although definitions of dyslexia vary across contexts, most definitions center on a significant discrepancy between reading achievement, particularly word recognition ability, and a measure of general cognitive ability or intellectual functioning.

The biological bases of dyslexia have gained significant research attention since the early 1990s. Many researchers have targeted the left hemisphere's perisylvian region, or the area surrounding the Sylvian fissure on the lateral surface of the cortex, in research examining morphology and planum temporale symmetry. *Morphology* refers to the pattern of gyri and sulci on the surface of the brain. Subtle deviations in perisylvian morphology, although not at a level of gross neurological significance, have been associated with dyslexia. Research on the biological basis of dyslexia has also focused on the planum temporale. Symmetry or rightward asymmetry in the length or size of the planum temporale have been associated with dyslexia. Polymicrogyri, additional small folds in the cortical surface, and heterotopias, neuronal migration errors, in this region have also been associated with dyslexia.

Although the perisylvian region has received significant research attention, it is not entirely clear why brains with symmetry or atypical morphology are more likely to be found in individuals with dyslexia. The symmetry noted in these brains may result from neuronal migration errors or poor pruning of redundant pathways. Because the individual has fewer functionally connected cells, those that are functional may be less able to compensate for other cortical atypicalities. Additionally, the individual may have fewer pathways available to compensate for the atypicalities.

Reading is a complex cognitive task that combines numerous skills, including attention, memory, phonological processing, rapid naming, and so forth. Consequently, any findings related to individual chromosomal involvement in the development of dyslexia might actually pertain to language tasks in general. Despite this caveat, research has implicated chromosomes 6 and 15 in dyslexia, resulting from the action of an autosomal dominant gene with variable expression and incomplete penetrance. Although there is significant evidence to support genetic involvement in dyslexia, environmental factors also play a role. Behavioral genetics research has suggested that slightly more than 50% of the variance in reading performance is the result of differences in genetic heritability.

Although research supports the involvement of genetics and the differences in the brain as being risk factors for dyslexia, these areas do not answer questions about the underlying cognitive processes that are involved in reading and that are aberrant in dyslexia. Research on dyslexia suggests that phonological processing and orthographic coding are two cognitive processes that play significant roles in reading ability and dyslexia.

Phonological processing allows an individual to hear and manipulate individual sounds in spoken language. Although there are only 26 letters in the English language, there are 44 phonemes. Phonological processing is part of

the larger skill of auditory perception and discrimination, but it is involved only with sounds used in speech. Rather than being one unitary skill demonstrable in a single behavior, phonological processing skills are actually a group of skills, including letter-sound association, rhyming, blending, segmenting, and sound replacement. Phonological processing skills are developing in children before they enter school, and these early skills appear to predict future reading achievement. Furthermore, these skills continue to develop as the child learns to read, such that the relationship between phonological processing and reading is symbiotic. Research with dyslexic children suggests that phonological deficits may be the core deficits impeding their reading acquisition. Furthermore, there is evidence to suggest that these skills are influenced by genetics and the underlying brain structures in the perisylvian region.

Orthographic processing is a second area of research investigation. It involves the interpretation of abstract representations, specifically, series of letters that form words during the reading process. Orthographic processing is most closely related to sight word reading, in which the individual does not use decoding strategies to read words but, rather, recognizes the entire word on sight. It appears to be influenced mostly by environmental factors, such as home reading environment, rather than genetic heritability. Functional magnetic resonance imaging (fMRI) has been employed to chart possible deficiencies in phonological and orthographic processes in the brain.

Intervention for dyslexia typically consists of remediation and compensation strategies. When children are diagnosed with dyslexia during the early school years, the emphasis is on teaching them phonetic skills to improve their decoding ability and teaching them to recognize sight words to increase reading speed. For many children, their reading improves and they are able to experience normal developmental outcomes, such as employment and, in some cases, higher-level education. For those individuals who do not develop adequate reading ability by adolescence and adulthood, the emphasis changes to include compensatory strategies. As adults, dyslexic individuals typically have access to books on tape and other compensatory approaches.

ALIENATION (POLITICAL)

Political alienation, or disaffection, is basically a feeling of dissatisfaction, disillusionment, and detachment regarding political leaders, governmental policies, and the political system.

Feelings of political disaffection comprise at least five components: *powerlessness* ("People like me don't have any say in what the government does"); *discontentment* ("For the most part, the government serves the interests of a few organized groups such as business or labor, and isn't very concerned about the needs of people like me"); *distrust* ("A large number of city and county politicians are political hacks"); *estrangement* ("When I think about the government in Washington, I don't feel as if it's my government"); and *hopelessness* ("The future of this country seems dark to me").

Three research findings seem germane to this conceptualization of political disaffection. First, these five components of disaffection are highly interrelated, with high levels of disaffection in one component correlating with high levels of disaffection in the other four. Second, two attitudinal dimensions appear to underlie these five components, with political powerlessness and estrangement forming a personal dimension of disaffection, while political discontentment, distrust, and hopelessness constitute a systemic dimension of disaffection. Third, in exploring the attribution of responsibility for political disaffection, one finds that individuals attribute the condition of the political system to the unintentional behavior of private citizens ("Citizens are uninformed about politics and public affairs because the government lies to them") rather than to the intentional behavior of public officials ("Politicians are unqualified for the positions they hold").

Two demographic factors have been fairly consistently found to relate to feelings of political disaffection: socioeconomic status and race. Thus, political alienation is more prevalent among the lower and working classes than among the middle and upper classes, and Blacks are more politically alienated than Whites.

Theories

At least seven explanations have been advanced to account for people's feelings of political alienation. *Complex organization theory* states that political disaffection will occur when people are unable or unwilling to participate politically in society, large formal organizations, or their communities. Two key causes of political alienation in society are a lack of primary relationships and an inability to belong to and participate in voluntary associations. When these two phenomena occur, feelings of political alienation result. *Mass society theory,* the principal variant of this explanation, suggests that modern society cannot be understood, does not offer achievable goals, is composed of people with dissimilar values, permits few personal satisfactions, and offers no sense of personal control. These societal characteristics lead in turn to political disaffection.

Social disadvantages theory, by comparison, holds that

people's social positions do not produce political disaffection; rather, disaffection results from the perceptions that people occupying social positions have of their relations with other people and other social entities. This theory would be supported by the evidence that socioeconomic status—that is, education, income, and occupation—is related to political disaffection, with such feelings occurring more frequently among individuals with less formal education, lower income levels, and blue-collar, manual occupations.

Personal failure theory postulates three preconditions for political alienation: (1) the individual must occupy a social position that limits his or her actions, (2) these limited opportunities must preclude the achievement of major life goals, and (3) the individual must perceive him- or herself as a failure in these attempts at goal attainment. In this case, failure to attain personal life goals does not engender political alienation; such a failure must be both socially caused and recognized by the individual for political alienation to occur.

Social isolation theory of alienation suggests that feelings of political disaffection are related to isolation from, or a lack of assimilation to, the political system. This lack of assimilation pertains to any social ties to any social object, not necessarily to society itself, and can be either cognitive or behavioral in nature. In addition, the social isolation can be either involuntary or voluntary, unconscious or conscious. In this instance, disaffection would be predicted from disinterest in politics, political apathy, weak partisanship, political ignorance, and a failure to vote.

In contrast to these sociological theories of political alienation, the *social deprivation model of disaffection* postulates that personal feelings of social deprivation lead to low self-esteem, which in turn results in high levels of political alienation. The two key elements in this theory—the linkage between perceived social deprivation and feelings of low self-esteem, and between low self-esteem and felt political alienation—have not been supported in surveys of White and Black adolescents.

Conversely, the *sociopolitical reality explanation* of political disaffection has been repeatedly supported in empirical research. This theory posits a direct link between perceptions of the sociopolitical system's functioning and feelings of political disaffection, with critical views of the system's operation being directly linked to felt disaffection. Although the sociopolitical reality model of political disaffection receives strong support, it manifests a major shortcoming, in that no account is provided for the nexus between a person's critical perceptions of systemic functioning and that person's feelings of political disaffection.

This connection is provided by the *systemic disaffection theory,* which suggests that three causal factors contribute to political alienation. First, critical perceptions of sociopolitical reality—that is, of economic and racial discrimination—must occur. Second, a politically irrational, perfectionistic response to the operations of the sociopolitical system must next occur, typically of a moralistic, rigid, grandiose nature. Third, psychological reactance, or perceived threat from the sociopolitical system, must also be elicited. This perceived threat to and/or loss of freedom will be particularly salient if the individual feels particularly susceptible to such a threat or loss, or views himself or herself as being comparable to others who have experienced a threat to or loss of freedom.

These three preconditions follow a specific causal sequence. Thus, critical perceptions of sociopolitical reality not only directly contribute to feelings of alienation from the sociopolitical system, but also lead to irrational political ideation and to psychological reactance. Next, irrational political ideation fosters high levels of psychological reactance and generates political alienation. Then feelings of psychological reactance also contribute to political alienation.

Consequences

A major concern among theories on the political disaffection process is the consequences of disaffection for the political system. Of the four attitudinal and behavioral consequences of political disaffection that are most frequently cited in the literature—attitudinal rightism and negativism, and behavioral apathy and extremism—only behavioral apathy has been firmly established in the research literature on conventional political activity. Thus it can be concluded that the politically disaffected, in their political attitudes and behavior, differ little from the politically allegiant. It also follows that the stability and viability of democratic political systems are not jeopardized by politically alienated segments of the population who may remain more politically apathetic than their peers.

ALL-OR-NONE LAW

Applied to the axon (single, relatively lengthy process) of a nerve cell or neuron, the all-or-none law states that transmission of a nerve impulse occurs either all the way or not at all. If the changes that produce the nerve impulse—that is, the movement of charged particles or ions—reach a certain threshold level, then the impulse (also called the *action potential* or *spike potential*) is conducted at a constant level from its origin to the end of the axon.

Another way the law is sometimes expressed is that axonal transmission is independent of the intensity of the stimulus that produces it. As long as the stimulus causes enough ionic movement to exceed a threshold, the nerve impulse occurs all the way, without decreasing as it travels

the length of the axon. A mild stimulus that surpasses the threshold produces the same nerve impulse as an intense stimulus. The nervous system codes the intensity of a stimulus by the rate of generation of action potentials, not by whether they occur, and also by the number of neurons activated in a given area. The greater the intensity, the larger the number of neurons activated and the more rapidly they generate action potentials. A neuron's action potentials are analogous to signals from a telegraph key: A neuron cannot send bigger or faster action potentials any more than a telegraph operator can send bigger or faster signals with the telegraph key.

The all-or-none concept applies to other excitable tissue as well, and the principle was first demonstrated in 1871 in heart muscle by American physiologist Henry P. Bowditch. In 1902, English physiologist F. Gotch discovered evidence for an all-or-none effect in nerves, but the effect was not convincingly proven until Edgar Douglas Adrian's work, for which he received a Nobel prize in physiology in 1932. Adrian's research was preceded by studies performed by K. Lucas, who actually named the law in a 1909 article.

Like most of the nervous system's so-called laws, the all-or-none law has exceptions. For example, some neurons can produce a series of action potentials that grow successively smaller, thus disobeying the law.

ALPHA RHYTHMS

Ensembles of synchronously active cortical neurons generate electromagnetic field potentials that can be measured by electroencephalography (EEG) or magnetoencephalography (MEG). The alpha frequency band is defined to be between 8 and 13 Hz (Berger, 1929; Adrian & Mathews, 1934). The classical alpha rhythm is prominent at electrodes overlying the occipital (visual) cortex and to a lesser extent over the posterior temporal and parietal areas. Alpha rhythm occurs in a condition of relaxed wakefulness with eyes closed, and it is depressed upon eye opening. The alpha rhythm disappears gradually during drowsiness, and different types of alpha activity appear in rapid eye movement (REM) sleep (Cantero, Atienza, & Salas, 2002).

Blind children do not develop the alpha rhythm. The alpha frequency matures and reaches the approximate average values of 8 Hz at age 3, 9 Hz at age 9, and 10 Hz at age 15. The interindividual variability is quite large. About 6–10% of healthy subjects have "low-voltage alpha activity," below 20 μV. In general, alpha amplitude is higher in children than in adults. Consistent amplitude asymmetries exceeding 2:1 are usually considered to be abnormal. Alpha variant rhythms with frequency of half or double the normal frequency may occur in some healthy subjects (Markand, 1990).

Alpha rhythm peak frequency correlates with cerebral blood flow and metabolism (Sulg, 1984), and low frequency is found in metabolic, infectious, and degenerative disorders, such as dementia of the Alzheimer type. Unilateral slowing or loss of alpha rhythm occurs in the presence of traumatic, neoplastic, infectious, or vascular lesions of one occipital lobe. Abnormal "alpha coma pattern" occurs in some comatose patients. The outcome is variable, depending on the underlying condition, but it is most often poor.

Other physiological rhythms within the alpha frequency band are the mu rhythm (9–11 Hz) recorded over the sensorimotor cortex (Niedermeyer, 1999) and the tau rhythm (Hari, 1999). Mu may be the only routinely recorded alpha-band rhythm in EEG of infants and small children. In order to see the proper alpha rhythm, passive eye closure or recording in darkness should by attempted.

Subdural and intracortical recordings, as well as source localization studies, have shown that the alpha rhythm has multiple generators within the cerebral cortex (Williamson, Kaufmann, Lu, Wang, & Karron, 1997). Although early studies suggested that the alpha rhythm was driven by feedback inhibition of thalamic relé cells (Andersen & Andersson, 1968), more recent studies suggest that both cortico-cortical and thalamo-cortical connections are of importance. It has been suggested that both intrinsic membrane ion channel properties and local neuron network properties determine rhythmic behavior (Lopes da Silva, 1991).

The coherence-function has become a popular tool because it reveals information about functional connectivity between different parts of the brain during various tasks and states (Gevins, Leong, Smith, Le, & Du, 1995). Volume conduction and the EEG-reference montage must be considered during interpretation. Event-related desynchronization (ERD) of central and occipital alpha rhythms represent activation of those cortical areas that are active in vision, motor preparation or selective attention (Pfurtscheller, Stancák, & Neuper, 1996). Event-related alpha-oscillations in visual and auditory cortex following visual and auditory stimuli respectively have been described (Basar, Basar-Eroglu, Karakas, & Schürmann, 1999).

Conflicting results have been published regarding the possible relationship between alpha frequency and cognitive performance (Markand, 1990; Klimesch, 1999). A recent study found no correlation between alpha peak frequency and intelligence dimensions (Posthuma, Neale, Boomsma, & de Geus, 2001). Some evidence suggest that slow (8–10 Hz) and fast (11–12 Hz) alphas reflect functionally different processes (Verstraeten & Cluydts, 2002). Biofeedback treatment aimed at alpha enhancement may relieve anxiety (Moore, 2000). The existence of a relationship between depression and frontal alpha asymmetry has been challenged recently (Debener et al., 2000).

Considerable progress has been made toward a better understanding of the basic mechanisms behind alpha

rhythms and brain function during recent years. Some data regarding alpha coherence seem to challenge the concept that cognitive events only are associated with gamma (30–100 Hz) activity (Nunez, Wingeier, & Silberstein, 2001). High-resolution EEG and MEG recording combined with mathematical methods and individual magnetic resonance brain imaging are exciting tools for future brain function research.

ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is a progressive neurodegenerative disease, affecting memory, intellectual functions, and behavior. The prevalence of Alzheimer's disease is increasing with the growing percentage of the population over age 65. Remarkably, 15% of persons over age 65, and up to 50% of persons over age 80, may meet diagnostic criteria for AD (Evans et al., 1996; Pfeffer, Afifi, & Chance, 1987). Approximately 14 million persons are expected to have AD by the middle of the twenty-first century.

The pathology of AD involves the degeneration of select cortical regions and ascending brain-stem systems, including the cholinergic basal forebrain. These structures exhibit pathological hallmarks of neurofibrillary tangles within neurons and extracellular senile plaques containing Aβ40 and Aβ42. There are other pathological changes, however, including synaptic and neuronal loss, vascular changes, granulovacuolar degeneration and alterations to endosomal/lysosomal systems, and signs of inflammation and oxidative stress (Terry, 1994).

Genetic research has provided key insights into the biology of AD. Early-onset familial AD is linked to mutations in the β amyloid precursor protein (APP), presenilin 1, and presenilin 2 (Hardy & Selkoe, 2002). Late-onset familial and sporadic AD is associated with Apo E. Increased amounts of Aβ42, derived from APP, resulting from mutations in APP and presenilins alike (Hardy & Selkor, 2002), may enhance Aβ aggregation (Jarrett & Lansbury, 1993). Apo E genotype influences AD susceptibility, perhaps via increased Aβ deposition (Schmechel et al., 1993). Numerous studies confirm that the ε4 allele increases AD risk and decreases age of onset (Corder et al., 1993; Farrer et al., 1997).

The clinical presentation of AD usually begins with

Table 1. NINDS-ARDA Criteria for Probable Alzheimer's Disease and *DSM-IV* Criteria for Dementia of the Alzheimer's Type

A. Include the following:
   1. Dementia established by clinical examination and documented by the Mini-Mental Test, Blessed Dementia Scale, or some similar examination, and confirmed by neuropsychological tests
   2. Deficits in two or more areas of cognition
   3. Progressive worsening of memory and other cognitive functions
   4. No disturbance of consciousness
   5. Onset between ages 40–90, most often after age 65
   6. Absence of systemic disorders or other brain diseases that in and of themselves could account for the progressive deficits in memory and cognition
B. The diagnosis is supported by the following:
   1. Progressive deterioration of specific cognitive functions, such as language (aphasia), motor skills (apraxia), and perception (agnosia)
   2. Impaired activities of daily living and altered patterns of behavior
   3. Family history of similar disorders, especially if confirmed neurohistopathologically

A. The development of multiple cognitive deficits manifested by both:
   1. Memory impairment (impaired ability to learn new information or to recall previously learned information) and
   2. One (or more) of the following cognitive disturbances:
      a. Aphasia (language disturbance)
      b. Apraxia (impaired ability to carry out motor activities despite intact motor function)
      c. Agnosia (failure to recognize or identify objects despite intact sensory function)
      d. Disturbance in executive functioning (i.e., planning organizing, sequencing)
B. Each of the cognitive deficits in Criteria A1 and A2 causes significant impairment in social or occupational functioning and represents a decline from a previous level of functioning.
C. The course is characterized by gradual onset and continuing cognitive decline.
D. The cognitive deficits in Criteria A1 and A2 are not due to any of the following:
   1. Other central nervous system conditions that cause progressive deficits in memory and cognition (e.g., cerebrovascular disease, Parkinson's disease, Huntington's disease, subdural hematoma, normal pressure hydrocephalus, brain tumor)
   2. Systemic conditions that are known to cause dementia (e.g., hypothyroidism, vitamin B12 or folic acid deficiency, hypercalcemia, neurosyphilis, HIV infection)
   3. Substance-induced conditions
E. The deficits do not occur exclusively during the course of a delirium.
F. The disturbance is not better accounted for by another Axis I disorder (e.g., Major Depressive Disorder, Schizophrenia)

memory loss and mild cognitive impairment, which slowly worsen over years (Cummings & Cole, 2002). In early stages there is frequent repetition of stories and questions, misplacing of belongings, geographic disorientation, dysnomia, and difficulty managing finances or handling complex tasks. Sleep disturbances, depression, psychosis, and other neuropsychiatric problems commonly evolve. Assistance is eventually needed for dressing, bathing, meals, and other activities. Individuals often become lost in familiar surroundings and have reduced comprehension. Late stages often bring agitation and aggression, profound cognitive impairment, and loss of control of bodily functions. These disabilities often lead to institutionalization, increased risk of decubitus ulcers, aspiration pneumonia, and urosepsis from indwelling catheters.

Diagnosis of AD is based on the clinical features and the exclusion of other etiologies (Knopman et al., 2001). Two commonly used diagnostic criteria are listed in Table 1. Confirmation of cognitive impairment is important. Common screening tools for dementia include the Mini-Mental State Exam, the Mattis Dementia Rating Scale, and the clock drawing test (Folstein, Folstein, & McHugh, 1975; Kirby et al., 2001; Mattis, 1976).

Laboratory testing is important in evaluation of cognitively impaired individuals to rule out other causes of dementia (Table 2). Blood tests evaluate metabolic, hormonal, and nutritional derangements. New tests can aid in diagnosis of atypical cases. Cerebrospinal fluid analysis of tau and Aβ42 provides reasonable sensitivity and specificity for AD (Andreasen et al., 2001; Hulstaert et al., 1999) but is limited by its invasiveness. Genetic testing for Apo E and presenilin is commercially available, but its role in AD diagnosis is often misunderstood. Apo E genotyping is not indicated for AD diagnostic testing (Liddell, Lovestone, & Owen, 2001; Post et al., 1997) and adds little to the sensitivity and specificity of clinical judgement. Many patients with sporadic late-onset AD do not have an ε4 allele, and many patients with an ε4 allele do not have AD. In families with autosomal dominant early-onset AD, genetic testing can often determine the mutation (Lidell et al., 2001), but these cases collectively account for less than 2% of all AD (Saunders, 2001). Presenilin testing should only be performed with appropriate genetic counseling.

Neuroimaging is essential to rule out conditions such as subdural hematomas, hydrocephalus, and space-occupying lesions (Small & Leiter, 1998). Noncontrast computed tomography or magnetic resonance imaging are suitable for most cases. Positron emission tomography and single photon emission computerized tomography scanning of patients with AD characteristically reveals hypometabolism in the parietotemporal region, even in preclinical individuals at high genetic risk for disease (Small et al., 1995). However, these studies are expensive and not widely available. They are most useful when attempting to discriminate AD from other neurodegenerative conditions that show distinct regional patterns of hypometabolism. Imaging research is

Table 2. Disease Processes That Should Be Considered in the Differential Diagnosis of Dementia and Their Principle Method of Evaluation

Treatable causes of dementia that must be excluded primarily by serologic studies:
- Neurosyphilis
- Hypothyroidism
- Vitamin B12 deficiency
- Folate deficiency
- Hypercalcemia
- Hypo- or hypernatremia
- Renal dysfunction
- Liver dysfunction
- Chronic drug intoxication
- HIV infection

Treatable causes of dementia that must be excluded primarily by neuroimaging studies:
- Normal pressure hydrocephalus
- Subdural hematoma
- Multi-infarct dementia
- Subcortical arteriosclerotic encephalopathy (Binswanger's disease)
- Space-occupying lesions (tumor, abscess, etc.)
- Demyelinating diseases (multiple sclerosis, PML)

Other causes of dementia that may be excluded by EEG:
- Subclinical seizures
- Creutzfeld-Jakob disease (CSF 14-3-3 protein also diagnostic)

Other causes of dementia that must be excluded primarily by clinical features:
- Pseudodementia (depression)
- Pick's disease and Frontotemporal dementias
- Parkinson's disease
- Progressive Supranuclear Palsy
- Diffuse Lewy Body disease
- Cortical-basal-ganglionic degeneration
- Huntington's disease

evolving rapidly, promising more sensitive and specific tools for future clinical use.

Current therapies for AD are primarily based on augmenting the central cholinergic system (Doody et al., 2001). Available acetylcholinesterase inhibitor drugs have similar efficacy. Donepezil, rivastigmine, and galantamine have been shown to be effective in several large double-blind placebo-controlled clinical trials (Dooley & Lamb, 2000; Lamb & Goa, 2001; Olin & Schneider, 2002). Many patients may not show immediate clinical benefit, but over time (e.g., 6–12 months) they tend to show less decline than untreated subjects. These drugs have efficacy for cognitive symptoms as well as for behavioral problems; they delay the need for institutionalization and also reduce the overall economic burden.

Other therapies employed in the treatment of AD include the use of vitamin E, an antioxidant that appears to delay progression of the disease (Sano et al., 1997). Epidemiological studies have provided indirect evidence that other medications are associated with reduced AD risk, including estrogen, nonsteroidal anti-inflammatory drugs (NSAIDs), statins, folic acid, and vitamin supplementation (Cummings & Cole, 2002; DeKosky, 2001; Kukull & Bowen, 2002). However, prospective clinical studies are essential to determine if these treatments are effective and safe. Unfortunately, prospective double-blind studies have failed to show efficacy of estrogen replacement or NSAIDs (Aisen, 2002; Mulnard et al., 2000); further study is necessary. Until safety and efficacy issues are addressed with prospective studies, precautions against use of any unproven agents for AD should be heeded because of the risk of serious adverse events.

Finally, psychotherapy and education are often needed to help families as they come to terms with a patient's changing abilities and experience the grief associated with perceived loss, and to provide more effective care (Cooke et al., 2001; Gitlin et al., 2001; Hepburn et al., 2001). Although the diagnosis may be perceived by some as catastrophic news, education and contact with community support such as the Alzheimer's Association and other such groups may help lessen the anxiety and fear of the unknown, and enable individuals to function better and longer within their families and in their own homes.

AMERICAN PSYCHOLOGICAL ASSOCIATION

The American Psychological Association (APA) is a scientific and professional membership association incorporated in the District of Columbia. Founded in 1892, the APA was the world's first national psychological association, and it remains the largest. In 1945, it reorganized to encompass several smaller psychological groups, broadening its mission but retaining the APA name.

The APA's expanded mission included professional as well as scientific issues and a concern for psychology's contributions to the public interest. A multifaceted structure was developed to reflect the diversity of the APA's membership and its expanded mission. These changes, and the growth of membership, also prompted the establishment in 1946 of a central office with an executive officer and staff to provide membership services.

Membership

In 2002, the APA had 155,000 members and affiliates. The members exercise their authority over Association affairs by voting directly for bylaw changes and for the APA president, and through the election of members to serve on the Council of Representatives. The membership consists of several classes: member, fellow, associate member, and affiliate. Affiliates, who are not members, include international members, students, and high school teachers.

Council of Representatives

The Council of Representatives (hereafter referred to as the Council) has full authority over Association affairs and

funds. Its members are elected by the APA's two primary constituencies: divisions, which are an integral part of the APA's structure, and state and provincial psychological associations (SPPAs), which are affiliates of the APA. The Council elects the recording secretary, the treasurer, and members of all standing boards and committees. It also confirms the appointment of the chief executive officer (CEO).

Board of Directors

The Council elects six of its members to serve with elected officers (president, past president, president elect, treasurer, recording secretary, and CEO ex officio), as members at large of the 12-person board of directors (hereafter, the Board), which manages affairs of the Association. Subject to the final authority of the Council, the Board oversees the Association's business, monitoring the annual budget and any budget deviations during the year, and acting for the Council between the Council's biennial meetings.

Boards and Committees

Much of the Association's work is done by volunteer members serving on boards, committees, and other groups, such as ethics, membership, accreditation, and so on. Committees generate proposals for new policies or new activities, which are submitted for review by the Board and then sent to the Council for final determination.

Divisions

When the APA reorganized in 1945, 19 divisions were established to reflect special interests of its members. By 2002, the APA had 53 divisions, ranging in size from 300 to 7,500 members, representing areas of specialization (e.g., clinical, counseling, developmental), special interest (e.g., international affairs, women's issues, psychology, law), and employment (public service, independent practice, the military). Each division has officers, bylaws, a newsletter, and an annual business meeting. Some have staff, administrative offices, and divisional journals and other publications.

State and Provincial Associations

Each state, two U.S. territories, and six Canadian provinces have psychological associations affiliated with the APA and are entitled to seek representation on the Council. These SPPAs range in size from 25 to 6,000 members. Most SPPAs have offices, a paid executive director, newsletters, annual meetings, and officers.

Central Office

The APA's central office is located a few blocks from the U.S. capitol. With nearly 500 employees, it provides staff for all boards and committees, operates a large publishing house, invests in stocks, manages real estate, and interacts with private, state, and federal agencies and organizations. In addition to annual revenues of $12 million in member dues and fees and $11 million from publications, it generates additional income of almost $15 million. General dues represent only 18% of the revenues needed to run the APA.

The executive vice president and CEO is responsible for the management and staffing of the central office and for running the business aspects of the APA. The Board oversees the work of the CEO and annually evaluates his or her performance.

Directorates

Central office activities are organized into eight units titled directorates and offices. The professional concerns of the membership are reflected in the four directorates: science, practice, education, and public interest. Each directorate has an executive director who is responsible for staff, programs, and a budget of several million dollars, and who reports to the CEO. Each directorate has a standing board or committee to provide general oversight for its activities.

Activities not fitting into one of the directorates are managed by one of four major offices: Public Communications, Central Programs, Financial Affairs, Publications and Communications, and the executive office.

The executive office provides coordination among the APA's offices and directorates, oversees all central office operations, maintains contact with national and international organizations, conducts all elections, and provides support to the officers, the Board, the Council, and APA governance.

APA Graduate Students

The APA graduate student organization (APAGS) is a student affiliate category, providing psychology students with the *Monitor* and the *American Psychologist,* and access to APA publications and services. APAGS permits psychology graduate students to participate actively in APA, to elect their own officers, and to carry out projects of interest. In 2002, there were approximately 59,700 student affiliates.

Annual Convention

The annual convention is held every August in different parts of the country, attracting 12,000 to 20,000 participants. The divisions primarily organize the program, each having an allotment of hours based on its size and previous member convention participation.

Federal Advocacy

Because of the importance of congressional actions and the activities of many federal agencies to psychology, the APA employs staff who specialize in advocacy and are trained to

provide information and assistance in policy development. They review proposed legislation, identify areas relevant to psychology's agenda, advocate on behalf of psychologists, and work with federal agencies to ensure that psychology participates in appropriate programs.

Interorganizational Activities

The APA maintains communication with a large number of psychology and related organizations worldwide. Each directorate maintains contact with U.S. psychological organizations relating to its domain, and the APA participates in many interdisciplinary coalitions for advocacy and information exchange. The Office of International Affairs publishes a newsletter for several thousand APA international affiliates, maintains contact with virtually all national psychological societies, and participates actively in international congresses, including sponsoring and organizing the 1998 International Congress of Applied Psychology.

RAYMOND D. FOWLER

AMERICAN PSYCHOLOGICAL ASSOCIATION *CODE OF ETHICS*

The American Psychological Association (APA) promulgated the first *Code of Ethics* for psychologists in 1953. Based on the work of a committee organized in 1947 (Canter, Bennett, Jones, & Nagy, 1994), this publication had further basis in the work of another committee, this one formed in 1938 and devoted to ethical concerns. The formalization and codification of ethical standards was ultimately a response to the increasing professionalization of psychology, a development that began during World War II.

The first *Code of Ethics* (APA, 1953) was developed using an empirical, critical-incident methodology (Hobbs, 1948), which had been unprecedented among associations. Rather than using an a priori method to determine ethical principles, the authors surveyed the membership of the association for descriptions of past incidents in which decisions with ethical implications had been made, and requested a discussion of the ethical issues involved. This material then formed the basis for many drafts of the first *Code of Ethics,* each of which was distributed to the membership for commentary before the final version was adopted.

Since the introduction of the original *Code of Ethics,* numerous revisions, either minor or major, have been adopted. These changes, regardless of scope, serve to keep the *Code* current and responsive to new issues, to changing views on traditional issues, and to legal imperatives that influence ethical behavior. It would be accurate to describe the *Code of Ethics* as a living document whose approach to ethics is influenced by current events rather than being based on universal ethical principles. Each revision of the *Code of Ethics* contains a set of ethical principles (or standards) without the inclusion of illustrative incidents.

The *Code of Ethics* presently in force was published in 1992 (APA, 1992), although a committee currently is working on a new revision. Although the critical-incident methodology was not employed for the 1992 edition, the revision was informed by the history of ethical complaints that had been filed, so that an empirical basis was built into the revision process. The alterations to the *Code* took 6 years and involved many iterations of the APA membership, the Ethics Committee, the Revision Comments Subcommittee, and the Council of Representatives of APA. The resulting document was intended to be accessible both to psychologists and to consumers of psychological services, and to provide guidelines that would increase the quality of psychological services and also reduce the risk of harm to the consumers.

The code of ethics of any professional association is enforceable only with regard to members of the association, yet such a code also informs the basis of many state boards' conceptions of ethics. Board members, in turn, are asked to make judgments on the professional conduct of licensed professionals. In psychology, the *Code* is the foundation of the ethical instruction mandated by accreditation for its students. Thus, the influence of the *Code* is far broader than its scope of enforceability. Similarly, although the maximum penalty that can be exacted for a serious violation of the *Code* is simply expulsion from the organization, this expulsion is publicly noted, other groups with relevant jurisdiction are informed (and may take independent action), and matters such as insurability are affected, so that the penalty is much more severe than expulsion by itself.

The 1992 *Code of Ethics* has two major sections, as well as introductory material. The first section of the *Code* consists of six General Principles, which, although aspirational rather than enforceable, can be used to interpret the enforceable standards that follow. These principles are concerned with the areas of competence, integrity, professional and scientific responsibility, respect for people's rights and dignity, concern for others' welfare, and social responsibility. Their approach informs the rest of the document, particularly the more specific principles that make up the largest portion of the document.

The General Principles' specific, directly enforceable translation is the Ethical Standards. The 102 standards are contained in eight sections; the first, General Standards, is potentially applicable to the professional and scientific activities of all psychologists, and is amplified in many of the subsequent standards. This section indicates, among other things, that the *Code* applies only to the professional, and not the personal, activities of psychologists, and that, when the *Code* conflicts with the law, the psychologist may choose to conform with the law, but *must* attempt to resolve the conflict in a manner consistent with the *Code.*

The second standard concerns evaluation, assessment,

or intervention. It is predominantly, but not exclusively, applicable to clinical activities. The standard concerning advertising and other public standards is much more permissive than previous Codes had been and was heavily influenced by rulings of the Federal Trade Commission. The fourth standard concerns therapy and may be the area of major concern to most practitioners. It is complemented by the next standard, which concerns privacy and confidentiality, although the latter standard goes beyond the clinical activities of psychologists. The sixth standard concerns teaching, training supervision, research, and publishing. Its presence makes clear that the *Code of Ethics* is not restricted in its scope to professional practice but is intended to be applicable to the activities of all psychologists. The seventh standard, forensic activities, is new, and reflects the increasing involvement of psychologists in forensic activities. It applies to all forensic activities, and not just the activities of forensic psychologists. This section has been an area of disproportionate action, perhaps because of the adversarial nature of the arena in which this activity takes place. The last standard addresses resolving ethical issues and indicates the responsibility of psychologists to be familiar with and to help uphold the ethical standards of the discipline.

Although the *Code* itself consists only of bare statements, an excellent commentary has been developed (Canter et al., 1994) for those who wish for further information about the meaning of the principles. It is only through the commitment of the individual psychologist to the *Code of Ethics* that psychology can progress toward a firm foundation in ethical and responsible conduct.

AMPA RECEPTORS

Introduction

AMPA ([RS]-alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptors belong to the subclass of glutamate receptors known as ionotropic or ion channel receptors (iGluRs), in addition to the kainic acid (KA), and *N*-methyl-D-aspartate (NMDA) families. AMPA receptors were originally called *quisqualate receptors* because of their affinity for quisqualic acid, derived from the Cambodian quisquala tree. However, the seaweed toxin kainic acid (KA) was also found to activate these receptors to a lesser degree. Further studies then found that [^{3}H]AMPA distinguished this group of receptors more clearly from [^{3}H]KA binding sites in brain tissue. Glutamic acid is the major endogenous ligand for the iGluRs, although additional so-called EAAs (excitatory amino acids), named for their generation of excitatory postsynaptic potentials (EPSPs), are also present in the brain, including L-aspartate, quinolinate, and homocysteate. The other current major subclass of receptors activated by glutamate, the metabotropic type (mGluRs), are guanine nucleotide binding protein (G-protein)–coupled and are voltage-gated as opposed to ion-gated. The AMPA receptor/channel complex and the KA and NMDA iGluR channel types are the main mediators of excitatory neurotransmission in the brain. They also have many roles outside the central nervous system.

Molecular Diversity of Structure

AMPA-type glutamate ion channels are synthesized in vivo from four subunits (GluR1-4 or GluRA-D). The GluR1-4 subunits are assembled in various combinations to form the protein structure of a channel, which is either homomeric (all the same subunit) or heteromeric (more than one type of subunit). The types of subunits assembled determine the functional characteristics of the channel, as will be noted further. The AMPA-type channels function in the neuronal or glial cell membrane to conduct the influx of ions (particularly Na^+, K^+, Ca^{++}) and rapidly desensitize in the ongoing presence of ligands.

The GluR1-4 subunit proteins belong to a single family of genes (based on sequence homology), yet each subunit is coded by a different gene, namely *GRIA1* (GluR1) at chromosome 5q32-33, *GRIA2* (GluR2) at 4q32-33, *GRIA3* (GluR3) at Xq25-26, and *GRIA4* (GluR4) at 11q22-33 (Dingledine, Borges, Bowie, & Traynelis, 1999).

The AMPA receptor subunits are structurally similar and have a similar transmembrane topology, possessing three transmembrane (M1, M3, and M4) domains and one reentrant membrane domain facing the cytoplasm (M2). The N-terminus is extracellular and the C-terminus is intracellular (Figure 1). The binding domain for ligand such as glutamate is in the pocket formed by S1 and S2. S1 is before M1, and S2 is after M3 in the transmembrane topology (Figure 1). Each of these four GluR1-4 subunits is diverse in its molecular variation via posttranscriptional and posttranslational mechanisms, which result in significant functional variations depending on brain region, developmental stage, and states of health or disease.

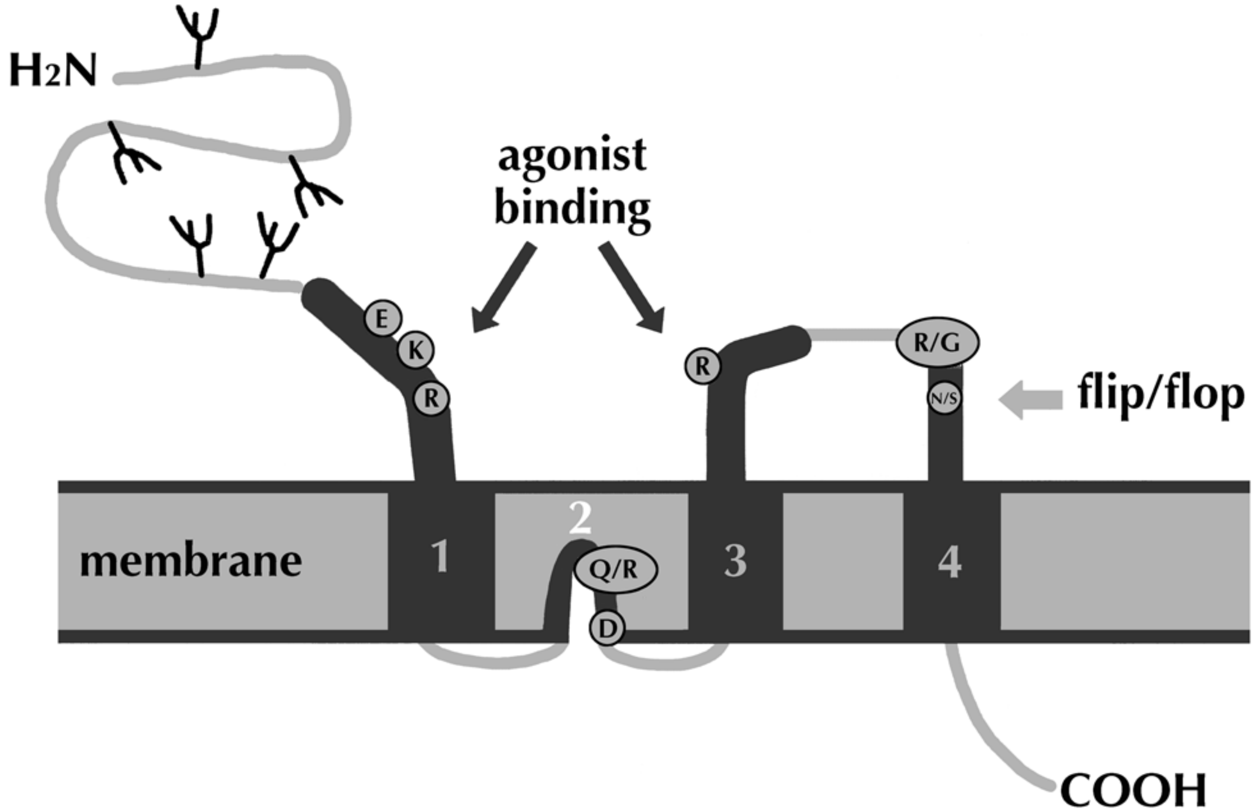

Figure 1. AMPA receptor topology. Q/R (glutamine/arginine) and R/G (arginine/glycine) are editing sites; N/S are asparagine (N) and serine (S) residues that confer specific desensitization properties (via cyclothiazide sensitivity) to the flip and flop modules; E (glutamate), K (lysine), and R (arginine) are amino acid residues that determine the binding site for glutamate and other EAAs.

Posttranscriptional (RNA) Modifications

Each subunit undergoes posttranscriptional modifications involving at least two mechanisms. One of these is the *alternative splicing* of mRNA. The resulting splice variants called *flip* (i) and *flop* (o) result from the splicing out of one of two possible modules within the mRNA. Flip and flop splice variants are responsible for significant structural and functional channel variation on the extracellular side of the membrane preceding TM4 (Figure 1). They are of vital importance in determining the desensitization properties of the receptor/channel complex. Another source of structural and functional variation is *RNA editing* at the *Q*/*R* and *R*/*G* sites in the mRNA. In domain TM2 of GluR1-4, a particular glutamine (Q607; codon CAG) may be edited enzymatically to an arginine (R607; codon CIG). This Q/R editing process is regulated by an adenosine deaminase enzyme (ADARA) by yet-unknown mechanisms and is more than 99% efficient in editing GluR2 in almost all brain regions (a physiologically important exception being Bergmann glial cells in the cerebellum), conferring the property of near impermeability to calcium ions, low single-channel conductance, and a nearly linear current-voltage relation. Calcium ion impermeability in most brain regions is essential for survival to prevent excitotoxic injury to neurons. A single edited GluR2 subunit in a heteromeric AMPA channel is sufficient to confer this protection. Recent evidence also shows that GluR2 release from the endoplasmic reticulum seems to be regulated by this editing process, lending dual importance to its role. GluR2-4 are also edited at an additional site called the R/G site, located near the flip/flop coding region, resulting in diminished and more rapid desensitization.

Posttranslational (Protein) Modifications

AMPA ion channels undergo *phosphorylation,* which may affect synaptic plasticity and is tightly regulated by phosphokinases such as PKA, PKC, CaMKII, and others. Phosphorylation generally potentiates AMPA receptor activation, with evidence that it occurs by keeping the channel open longer or more often. AMPA receptors also contain 4 to 6 *N-glycosylation* sites that influence binding of ligands to the receptor pocket, with effects that depend on the type of ligand and the subunit's flip/flop specification.

Protein-Protein Interactions Involving AMPA Receptor Proteins

Recent experimental findings have begun to outline a rich complex of protein interactions involved in the trafficking,

assembly, clustering, and membrane anchoring of AMPA subunits, presumably crucial to maintenance of the appropriate number and functional types of AMPA channels. Important interacting proteins include the PDZ-domain bearing proteins GRIP1 (glutamate receptor interacting protein), GRIP2, PICK1 (protein interacting with C kinase), ABP (AMPA binding protein), EphrinB1, liprin/SYD2 family proteins; the secreted lectin and immediate early gene Narp (neuronal activity-regulated pentraxin); and NSF (N-ethylmaleamide-sensitive factor). The protein-protein interactions carried out by these entities in the AMPA family appear to be analogous to those in other glutamate receptor subclasses (e.g., PSD-95 and NMDA channels) and in other receptor families (e.g., agrin and acetylcholine receptors).

Developmental Aspects of Diversity

The GluR1-4 subunits and their molecular variants (Figure 2) appear to follow specific ontogenetic, regional, and disease-specific patterns presumably to meet the current needs of the organism. For example, the edited (i.e., calcium ion impermeable) form of GluR2 becomes increasingly prevalent with maturity, as required to restrict calcium ion flux through the AMPA-type channels. Vulnerability to the development of seizure disorders is hypothesized to be related to the lower concentrations of edited GluR2 early in development. The flip and flop isoforms are also observed to follow developmental lines. Flip forms are more prevalent before birth and continue their expression into adulthood in rodents, whereas flop forms begin at low levels of expression until postnatal day 8 and then upregulate to a level similar to the flip variants. The flip forms tend to desensitize more slowly and to a lesser degree than flop forms.

AMPA Receptors in Health

Glutamate receptors contribute to processes of normal development, synaptic plasticity, learning, and excitatory neurotransmission of humans, nonhuman primates, rodents, Drosophila species (fruit fly), and C. elegans (roundworm). AMPA receptors participate with NMDA receptors in the coordination of long-term potentiation (LTP) and long-term depression (LTD), which are strongly suspected to subserve memory functions, including working memory, and govern experience-dependent synaptic plasticity by the rapid cycling of AMPA receptors into and out of the cell membrane via complex protein-protein interaction mechanisms (Luscher, Nicoll, Malenka, & Muller, 2000) Glutamate neurons project from most cerebral cortical regions to other areas of cortex, the basal ganglia, the brain stem ventral tegmental area, and other sites. This strongly suggests powerful local and global organizational and regulatory functions for the AMPA and other glutamate receptor subtypes in the brain.

AMPA Receptors in Disease

A recently proposed model of glutamate excitotoxicity highlights the importance of molecular diversity of AMPA subunit expression. It hypothesizes that cells are vulnerable to injury from excessive Ca^{++} influx after any of a number primary insults affecting the expression of edited GluR2 subunits (such as ischemia, hypoxia, hypoglycemia, or epilepsy). AMPA receptor expression is also altered under conditions of stress in the hippocampus. Perhaps a peak in the expression of AMPA receptors at 20 to 22 weeks of gestation in the human may increase vulnerability to excitoxicity at that time, because AMPA receptors have been shown to increase during the prenatal period in rats, when there is also observed a greater vulnerability to excitotoxic injury.

In Rassmussen's encephalitis, a severe childhood form of epilepsy often requiring cerebral hemispherectomy because of its poor response to available anticonvulsive regimens, recent evidence supports an autoimmune mechanism involving the GluR3 subunit as an autoantigen.

Thus, current evidence supports roles for AMPA receptor involvement in excitotoxic injury through various pathophysiologic mechanisms such as epilepsy, stroke, ischemia, hypoxia, trauma, extreme stress, hypoglycemia, or hypercortisolemia, as well as in neurodegenerative diseases (e.g., Huntington's disease, Alzheimer's disease, Parkinson's disease). Pathophysiological roles for AMPA receptors have been suggested, and are under continuing study, in other neuropsychiatric disorders such as mood disorders, Schizophrenia, and anxiety disorders.

AMPA Receptors as Pharmacotherapeutic Sites

AMPA receptors are widespread in the brain, including most regions of the cerebral cortex, hippocampus, amygdala, thalamus, hypothalamus, brain stem, and spinal cord. The regional variations in expression of the subunits, splice variants, and editing efficiency are apparent and are probably involved in local and global network function. AMPA receptors are being studied as potential therapeutic targets in diseases such as Alzheimer's disease, cerebrovascular disease (preventive and poststroke), epilepsy, schizophrenia, neural trauma, and other conditions involving cognitive impairments. Such promise has been raised by the successes reported for AMPA agonists (*AMPAmimetics* or *AMPAkines*) to enhance maze learning in age-associated memory impairment in mice and for antagonists (*blockers*) to prevent the spread of necrosis in ischemic events. Agonists (such as CX516 and aniracetam) and antagonists of varying specificity for AMPA receptor variants are being studied, with goals of safer and more effective treatments for direct injury prevention due to toxins, ischemia, hypoxia, physical and emotional trauma, hypoglycemia, hypercortisolemia, neurodegenerative mechanisms, neurodevelopmental disorders, cognitive disorders, and epilepsy. A whole new array of selective clinical pharmacotherapeutics are based on allosteric modulators that are noncompetitive AMPA receptor antagonists, such as the 2,3-benzodiazepines GYKI 52466, GYKI 53773, and LY404187 may be clinically useful for treatment of movement disorders (like spasticity and Parkinson's disease), epilepsy, ischemia, and a wide variety of neurodegenerative diseases. Cognition enhancers such as aniracetam and CX516 may be useful for improvement of the cognitive deficits of disorders ranging from Alzheimer's disease to Schizophrenia. Pharmaceutical chemistry is advancing to the level of GluR1-4 subunit and splice form specificity, which is bringing a large number of drugs closer to clinical trials for some of the most common and devastating brain pathologies. Future work will hopefully also begin to elucidate the regulatory mechanisms behind GluR1-4 subunit and splice form assembly, homeostasis, regional specificity, and region-to-region signaling, of which very little is currently known.

AMPUTEES AND PHANTOM LIMB PAIN

Amputation of a body part can result in several forms of disordered sensation. These can be characterized as phantom sensation (nonpainful sensation referred to the amputated limb or body part), stump pain (pain at the amputation site), and phantom pain (pain referred to the amputated limb or body part). Phantom pain is defined as "pain referred to a surgically removed limb or portion thereof" by the International Association for the Study of Pain Task Force on Taxonomy (Merskey & Bogduk, 1994). It is characterized by continuous cramping, aching, burning sensations and painful loss of sensation often described as "pins and needles." It is often associated with stump pain. Prevalence varies, with reports of pain experience in up to 80% of amputees (Warton, Hamann, Wedley, & McColl, 1997). Episodes may last seconds to days and recur from a few times per year to hourly. Further information on the topic can be obtained from a recent review (Nikolajsen & Jensen, 2001).

The mechanism for development of phantom pain is debated, but there is agreement that it is related to pain in the limb prior to amputation, often referred to as "pain memory" (Nikolajsen, Ilkajaer, Kroner, Christensen, & Jensen, 1997). It has been stated in several case reports that the pain may be similar to that experienced several years before the amputation. Indications from the Nikolajsen study are an increased incidence of phantom pain in the first six months following amputation in patients who experienced preoperative pain, compared to those who did not. This correlation no longer existed 2 years following amputation. The authors concluded that there may be a relationship between intensity of preamputation pain and presence of phantom pain, but presence of preamputation pain may not be related to duration or nature of phantom pain.

Painful conditions of a neurogenic nature often present with similar symptoms, but the diversity of etiology of the conditions is too great to permit them to be described in global terms. In an attempt to describe the development of phantom phenomena, Melzack described the concept of a "neuromatrix" (Melzack, 1990). This involves a network of neurons that link different areas of the brain, including the somatosensory cortex, the thalamocortical area, and the limbic system. Input from the periphery and the cortex itself is coprocessed by these areas and shared with other regions of the brain to develop an overall picture of the intact body. Melzack suggested that the neuromatrix may maintain a long-term representation of the amputated limb.

Cortical reorganization has been implicated in the etiology of phantom pain and may help to explain why some patients experience phantom pain while others do not (Birbaumer et al., 1997). For many years it has been demonstrated in case reports that sensations in the phantom limb can be elicited by stimulating anatomically unrelated areas. For example, touching an area on the face may cause

the patient to experience sensation in the phantom finger. This suggests that the cortex is receiving stimuli that, via neuronal reorganization, it perceives to originate in the phantom limb. Advanced neuromagnetic imaging techniques have permitted the demonstration of cortical reorganization in patients experiencing phantom pain. No corresponding cortical reorganization has been demonstrated in amputees not experiencing phantom pain. Cortical reorganization in patients with phantom pain was reversed following the administration of a regional anaesthetic block in those patients whose pain was resolved by the block (Birbaumer et al., 1997). This capacity to reverse cortical reorganization, even after prolonged periods of time, provides hope that effective treatments for phantom pain could be developed. *Telescoping,* described as the gradual shrinking and eventual disappearance of the phantom limb, has also been described. It is thought that this phenomenon may also be attributed to ongoing cortical reorganization over time.

Phantom limb pain is difficult to manage, with no individual treatment gaining universal acceptance. Treatment approaches for phantom pain include surgery, pharmacological management, physical therapies, and psychological interventions. Surgical procedures that attempt to cut or ablate the pain pathways have little if any benefit. However, surgical implantation of electrodes to stimulate the spinal cord and various parts of the brain may be of value in treating patients with phantom limb pain that is unresponsive to other treatments (Saitoh et al., 2000). Pharmacological management of phantom limb pain can involve drugs from many different classes, such as tricyclic antidepressants, opioids, benzodiazepines, antiarrythmics, anticonvulsants, antipsychotics, peptides (e.g., calcitonin), and NMDA-receptor antagonists (e.g., ketamine). In all cases, successful management in small-scale studies has been reported. Drug combination therapies are also used. In addition, regional anaesthetic nerve blocks (Birbaumer et al., 1997) and epidural and intrathecal blocks (Omote, Ohmori, Kawamata, Matsumoto, & Namiki, 1995) have been used to manage phantom limb pain. In many cases the effect of regional, epidural, or intrathecal block significantly outlasts the duration of the block, suggesting a long-term modulatory influence on the pain mechanism. One of the most common physical therapy approaches has been use of transcutaneous electrical nerve stimulation (TENS) for symptomatic relief. Acupuncture has also been used. Recent studies have demonstrated that active use of a functional limb prosthesis is effective in reducing phantom limb pain, possibly due to reversal of cortical reorganization resulting from activity of the limb (Weiss, Miltner, Adler, Bruckner, & Taub, 1999). Psychological issues related to loss the of limb, such as grief, may increase pain. Development of effective coping strategies has been shown to reduce pain in small studies (Pucher, Kickinger, & Frischenschlager, 1999).

It is likely that a multifaceted approach to pain management will be most effective, but further research is required to better understand the pain-causing mechanisms and determine effective treatment protocols for this common and difficult clinical problem.

AMYGDALA

The amygdala is a collection of nuclei located along the medial wall of the temporal lobe. Amygdaloid nuclei are classified as either cortexlike or noncortexlike based on neuronal morphology. The cortexlike nuclei, which include the lateral, basal, accessory basal, periamygdaloid, amygdalohippocampal area, and cortical nuclei, possess pyramidal-

like neurons similar to the pyramidal neurons of the cortex. The noncortexlike nuclei, which include the central and medial nuclei, possess neurons similar to the medium spiny neurons of the striatum and do not possess pyramidal-like neurons. Each of the amygdaloid nuclei has distinct inputs and outputs, suggesting that they serve distinct functional roles. However, the amygdaloid nuclei are also interconnected, suggesting that circuitry within the amygdaloid nuclei allows the amygdala to function as a unit in processing information. In regard to information processing within the amygdala, sensory input is received primarily through the cortexlike nuclei, and output is relayed primarily through the noncortexlike nuclei.

The amygdala is a component of the limbic system, which is thought to be involved in learning, memory, emotion, and motivation. The amygdala receives highly integrated unimodal and polymodal sensory information and sends information to cortical, limbic, endocrine, autonomic, and motor areas. These anatomical connections suggest that the amygdala is ideally located for monitoring the environment and modifying physiological and behavioral responses accordingly. Indeed, the amygdala has been implicated in processing emotional stimuli, associative learning, memory, attention, arousal, and social behavior.

One of the first clues regarding the function of the amygdala was that symptoms of the Klüver-Bucy syndrome, including a loss of reactivity to emotional stimuli, were produced by amygdala lesions in monkeys. These monkeys willingly approached fear-inducing stimuli. This finding suggested that the amygdala is involved in processing the emotional significance of environmental stimuli. Several additional lines of evidence support this idea. Unilateral lesions of the amygdala along with cuts through the optic chiasm and forebrain commissures produce a disconnection of visual input from one eye to the amygdala. Monkeys restricted to viewing threatening stimuli through the eye disconnected from the amygdala remain calm and fail to show defensive reactions to the stimuli. When the same monkeys are allowed to view the fearful stimuli through the other eye, however, they exhibit appropriate defensive reactions, which suggests that the intact amygdala processes the emotional significance of the stimuli. The amygdala also plays a role in processing reward, because animals will perform an operant response to obtain mild stimulation of the amygdala, and lesions of the amygdala disrupt appropriate responding to changes in reward magnitude. Electrophysiological studies indicate that amygdala neurons are more responsive to complex emotional stimuli than simple neutral stimuli. In humans, imaging studies have demonstrated that the amygdala is activated by photographs of facial expressions and is more strongly activated by fearful faces than angry or happy faces. Furthermore, patients with amygdala damage have difficulty comprehending the emotional category and intensity of facial expressions. Moreover, stimulation of the amygdala in humans and animals evokes emotional responses and species-specific defense reactions, respectively.

The amygdala is also involved in associative learning through which initially neutral stimuli gain biological significance (i.e., survival value). The best-documented example of this associative learning is fear conditioning, in which a fearful event or stimulus (unconditioned stimulus) is paired with an initially neutral stimulus (conditioned stimulus). Subsequently, the conditioned stimulus comes to elicit conditioned fear responses in the absence of the unconditioned stimulus. These responses include conditioned freezing behavior, startle reactivity, and autonomic responses. There are strong and converging lines of evidence that the amygdala is involved in fear conditioning.

Although the amygdala may play a prepotent role in information processing and associative learning involving aversive fearful stimuli, its function is not limited to aversively motivated learning, because it also plays a role in stimulus-reward associations. For instance, monkeys exhibit emotional reactions when presented with familiar palatable foods; however, they exhibit relatively little interest when presented with novel palatable foods. Upon tasting the novel foods, the monkeys learn to associate other sensory aspects of the foods with the taste of the foods. Subsequently, exposure to the foods elicits learned emotional responses and preferences for certain foods over other foods. Amygdala lesions disrupt acquisition of emotional responses and preferences for the novel palatable foods, suggesting that the animals are unable to associate the appearance of a new food with its palatability. Through stimulus-reward associations, initially neutral environmental stimuli gain incentive salience via their ability to predict reward. Consequently, these stimuli come to produce incentive motivation, reflected by approach behaviors, as well as secondary reinforcing effects. These behavioral effects are also disrupted in animals with amygdala lesions, particularly lesions of the basolateral amygdaloid nuclei. For instance, animals with basolateral amygdala lesions fail to acquire operant responding reinforced by presentation of a stimulus light (secondary reinforcer) that had been paired previously with delivery of a water reinforcer (primary reinforcer).

Memory for emotional events is superior to memory of nonemotional events. This phenomenon may be due, at least in part, to hormones that are released in response to stress that modulate effects on memory by binding to receptors in the amygdala. Stress hormones, such as epinephrine and corticosterone, produce a dose-dependent enhancement of memory when given after training. Posttraining administration corresponds to the time at which these hormones are naturally released in response to a stressful event and at which consolidation of the memory for the event occurs. Amygdala lesions abolish the memory-enhancing effects of these hormones, and direct injection of the hormones into the amygdala produces memory-

enhancing effects. Psychomotor stimulants, such as amphetamine, may also modulate learning and memory evident as enhancement of responding for secondary reinforcers. Lesions of the central amygdala disrupt psychomotor stimulant-induced enhancement of responding for secondary reinforcers.

The amygdala, particularly the central nucleus, is involved in modulating attention and arousal. The central nucleus of the amygdala projects to several brain regions that are thought to be involved in attention and arousal, including cholinergic basal forebrain neurons, autonomic regulatory nuclei in the medulla, and the lateral tegmental area of the brainstem. In rabbits, a conditioned stimulus predictive of an aversive shock produces an increase in spontaneous firing of amygdala neurons that correlates with excitability of cortical neurons as measured by cortical electroencephalogram (EEG) activity. The cortical EEG activity is thought to reflect an increase in attention. Evidence from functional magnetic resonance imaging studies in humans suggests that the amygdala responds to stimuli processed at a subconscious level. Specifically, subjects given very brief presentations of happy or fearful faces followed immediately by longer presentations of neutral faces report seeing only the neutral faces, yet the amygdala is more strongly activated when the neutral faces are preceded by fearful faces rather than happy faces. These findings suggest that the amygdala constantly monitors the environment for biologically relevant stimuli and may modulate moment-to-moment levels of attention. Many conditioned responses mediated by the amygdala, including conditioned autonomic responses and an arrest of ongoing activity, may serve to enhance attention to environmental stimuli. Furthermore, lesion and brain stimulation studies across species suggest that the amygdala is involved in orienting responses to environmental stimuli.

The amygdala plays an important role in social behavior. In general, stimulation of the amygdala elicits rage and attack behaviors, whereas lesions of the amygdala decrease aggressive behaviors across species. Stimulation and lesion studies also suggest that the amygdala is involved in social rank and affiliation, as well as sexual and maternal behaviors. Radiotelemetry data from a social group suggest that electrical activity of the amygdala is strongest when animals are being chased or aggressed upon or given ambiguous social information.

Amygdala dysfunction has been implicated in a number of neurological and psychiatric disorders. The amygdala is among several structures in the temporal lobe that are involved in epileptic seizure disorders. Repeated electrical or pharmacological stimulation of the amygdala induces the development of seizures. This experimentally induced seizure activity is referred to as *kindling* and is used as an animal model of epilepsy. The amygdala has also been implicated in other disorders known to involve temporal lobe pathology, including Schizophrenia and Alzheimer's disease. Imaging studies have indicated that amygdala volume is reduced in patients presenting these disorders. The amygdala likely plays a role in depression, anxiety, and Post-Traumatic Stress Disorder. Most antidepressant and anxiolytic medications produce effects via either benzodiazepine, norepinephrine, or serotonin receptors; the amygdala has a large population of these receptors. Furthermore, direct amygdaloid injection of benzodiazepine anxiolytic drugs reduces behavioral reactions that are thought to reflect fear and anxiety. Moreover, imaging studies have found that depressed patients exhibit an increase in metabolic activity in the amygdala that correlates with measures of depressive symptoms and is reduced by antidepressant treatments. The amygdala has also been implicated in the reinforcing effects of drugs of abuse. Furthermore, imaging studies suggest that the amygdala probably plays a role in the ability of drug-associated stimuli (e.g., drug paraphernalia) to elicit drug craving.

ANALYSIS OF COVARIANCE

The analysis of covariance (ANCOVA) has goals similar to those of analysis of variance; that is, it uses estimates of variability to test hypotheses about group means. However, ANCOVA differs from standard analysis of variance (ANOVA) because it uses not only information about the dependent variable, *Y,* but also information about an additional variable, *X,* called the *covariate,* which is correlated with the dependent variable. The ANCOVA procedure attempts to control statistically for differences in the covariate that would result in error variability and hence would reduce the efficiency of an ANOVA. The potentially greater efficiency of ANCOVA is obtained at the cost of additional complexity and stronger assumptions that must be made about the data. ANCOVA results are also frequently misunderstood.

Consider an example. Suppose we wish to test the effectiveness of four different software packages designed to develop problem-solving skills in fourth graders. Children are randomly assigned to work with each of the packages, and the dependent variable, *Y,* is the score on a problem-solving test given after the students have worked with the pack-

ages for 3 months. We also have available scores, X, on a pretest of problem-solving skills given before the children started working with the packages. Suppose we use ANOVA to test the null hypothesis that the software packages are equally effective. The means of the instructional groups will reflect not only the effects of the software packages, but also other sources of variability, including individual differences in problem-solving ability. The ANOVA can be thought of as a test of whether a model in which there is a treatment effect—that is, a component corresponding to the effect of working with one of the packages,

$$Y_{ij} = \mu + \alpha_j + \varepsilon_{ij}$$

—accounts for the data better than a restricted model in which there are no treatment effects,

$$Y_{ij} = \mu + \varepsilon_{ij}$$

where Y_{ij} is the test score of the ith participant in the jth treatment (here, software package) group, m is a common component, α_j is the effect of the jth treatment, and ε_{ij} is the error variability associated with the score. The larger the error variability, the more the treatment effects will be obscured. Because the children were *randomly* assigned to treatment groups, preexisting individual differences in problem-solving ability will not differ systematically across groups; however, they will contribute to the error variability and, thus, to the between-group variability. If all children had equal problem-solving ability (indicated by equal scores on the covariate) before working with the software packages, we would have a much better chance of assessing how effective the packages were. ANCOVA attempts to remove the component of the dependent variable predictable on the basis of the pretest by adding a regression component to each of the above models. It tests the model

$$Y_{ij} = \mu + \alpha_j + \beta(X_{ij} - \overline{X}) + \varepsilon_{ij}$$

against the restricted model

$$Y_{ij} = \mu + \beta(X_{ij} - \overline{X}) + \varepsilon_{ij}$$

where β is the regression coefficient or slope. An increase of power may be achieved because, if the treatment and error components are adjusted by removing the variability accounted for by the regression on X, the test statistic may be much larger. In effect, the ANOVA tries to assess whether there would be a treatment effect if all of the children had equal scores on the covariate.

Assumptions and Interpretation

Assumptions of normality and homogeneity of variance similar to those in ANOVA are made. However, additional assumptions that follow from the attempt to statistically control for differences in the covariate are required.

Linearity and Homogeneity of Regression Slopes

ANCOVA adjusts for differences in the covariate by removing variability accounted for by a linear regression on the covariate. If there is a nonlinear component to the relationship between X and Y, the ANCOVA tests will be biased. Moreover, it is assumed that the same regression adjustment is appropriate for each treatment group. Unless the slopes of the regression equations of Y on X are the same for each treatment group, ANCOVA should not be used. If there are different slopes, the interesting question is not what would happen if all the participants had the same score on the covariate, but rather, what would happen at different values of the covariate. A test for homogeneity of regression slopes should be conducted before an ANCOVA is performed.

Assumption of the Independence of Treatment and Covariate

It is not possible to interpret the results of an ANCOVA if the covariate varies systematically with the treatment effect. Using X as a covariate removes any part of Y predictable by a linear regression on X. However, if the value of X depends on the treatment condition, performing an ANCOVA will remove not only "error" variability, but also part of the effect of the treatment itself.

Suppose that in the example of the software packages students could choose to spend extra time working with the packages, and we desired to control for the amount of time they spent. However, time spent working with each package might reflect how understandable, interesting, and helpful the package was. Therefore, any adjustment based on the covariate would tend to remove part of the treatment effect. There is no substitute for conducting a true experiment in which both software package and time spent are independent variables.

Random Assignment to Treatment Conditions as Opposed to Using Intact Nonequivalent Groups

In ANCOVA, the distinction between randomized and nonequivalent group designs is important. When participants are randomly assigned to groups, groups should not vary systematically on the covariate, and interpretation is straightforward. However, when intact groups that differ on the covariate are assigned to different treatments, the treatment is confounded with characteristics of the group, and the results of an adjustment may be not be interpretable. Any adjustment based on the covariate will result in adjustments of any correlated characteristics as well, and will result in the kinds of difficulties of interpretation that occur in correlational research.

ANALYSIS OF VARIANCE

Analysis of variance (ANOVA) is one of the most commonly used statistical techniques in psychological research. The basic approach (and the reason for the name of the procedure) is to use estimates of variability to test hypotheses about group means.

To be more specific, consider an experimental design with a single factor (independent variable) that has, say, four levels. Suppose that the scores at each level are the numbers of items correctly recalled by participants in a memory experiment and the factor is learning strategy; that is, the levels of the factor correspond to different learning strategies. Each learning strategy can be thought of as being associated with a hypothetical population of scores: all the scores that have been, or could be, obtained using the strategy if the experiment were conducted over and over again. If the participants in the current experiment are appropriately chosen and assigned to the learning groups, the scores actually obtained in the four groups can be thought of as random samples from the populations associated with the different strategies. ANOVA can be used to test the null hypothesis that the means of the populations corresponding to the different strategies are all the same. That is, ANOVA provides a procedure for deciding whether the data collected in the experiment provide sufficient evidence to reject the null hypothesis, so that the strategy factor can be considered to be *statistically significant.*

Even if the null hypothesis was true, we would not expect all the sample means in our experiment to be equal. Any true differences among the different strategies will be obscured by random error variability in the obtained scores. That is, scores may differ from one another not only because they are associated with different learning strategies, but also because of a possible host of additional variables. For example, some participants might be better learners than others or be more motivated to perform well in the experiment. Perhaps for some participants there was background noise or other factors that interfered with learning present during the experiment. Because of this uncontrolled "error" variability, even if participants were assigned randomly to groups so that the groups would not differ systematically, the more talented or motivated participants would not be distributed exactly evenly across the groups, so the group means would be expected to differ from one another. The ANOVA procedure attempts to determine whether the group means associated with the different levels of an independent variable or factor differ from one another by more than would be expected on the basis of the error variability.

The mean of the variances of the scores *within* each group provides one estimate of the error variability. If the null hypothesis is true, the variability *among* the group means can be used to generate another estimate of the error variability. Under certain assumptions, the ratio of these two estimates is distributed as the F distribution if the null hypothesis is true. If the null hypothesis is *not* true, the estimate based on the group means should be larger than that based on the within-group variability because it includes not only random variability but all systematic variability due to the difference in the population means, and the ratio of the estimates should be larger than would be expected from the F distribution. In standard usage, if the value obtained for the ratio of the two estimates would place it in the extreme upper tail (the usual criterion is the upper 5%) of the F distribution, the null hypothesis is rejected.

ANOVA can deal with the effects of several factors in the same analysis. If we apply ANOVA to a design with two factors, we can test whether each is significant. Moreover, we can test whether there is a significant *interaction* between the factors—that is, whether there is a joint effect of the two factors that cannot be determined by considering each factor separately (see the entry dealing with factorial designs).

The null hypotheses tested by an ANOVA are very general. For tests of a *main effect,* the null hypothesis is that the population means of a factor are all equal. For tests of the interactions of two or more factors, the null hypothesis is that the joint effects—that is, the effects that cannot be obtained by adding up the main effects of the factors in question—are all 0.

There are many different kinds of ANOVA designs. When each subject provides a single score at only one combination of levels of the factors in the design, we have what is called a pure *between-subjects design.* When each subject provides a score at every combination of levels of the factors in the design, we have a pure *within-subjects* or *repeated-measures design.* It is common to encounter *mixed designs,* in which a given subject provides scores at all levels of one or more within-subjects factors, but at only one level of one or more between-subjects factors.

ANOVA is commonly employed to analyze the data from experiments. It is less appropriate for data obtained from observational research, because ANOVA treats all factors as categorical and uncorrelated.

ANALYTICAL PSYCHOLOGY

Analytical Psychology is the name Swiss psychologist Carl Gustav Jung (1875–1961) gave to his theoretical and methodological approach to the psychology of the unconscious following his break with Freud and psychoanalysis in 1913. Unlike psychoanalysis, analytical psychology does not understand the structure of the unconscious to be limited to contents that were initially a part of consciousness. Although it does not deny the psychoanalytic view that the unconscious includes contents that were once conscious, it holds that in addition to these the unconscious includes contents not yet capable of becoming conscious (i.e., symptoms) and contents incapable of ever becoming fully conscious (i.e., the symbolic manifestation of the archetypes of the collective unconscious). Moreover, analytical psychology maintains that the dynamics at issue in the formation of the unconscious are not exhausted by repression. Analytical psychology contests neither the psychoanalytic account of the *felt* incompatibility between conscious and preconscious (as well as unconscious) contents, nor the consequent mechanism of repression resulting in the dissociation of the latter contents from consciousness. However, it maintains that an additional dynamic, rooted in the inability of consciousness to *apperceive* psychic contents, also results in psychic contents having a subliminal and therefore an unconscious status. Apperception is defined by analytical psychology as the psychic process whereby new contents are assimilated into consciousness on the basis of their similarity to the contents already existing in consciousness.

Attitude Types and the Four Functions of Consciousness

Analytical psychology diverges from psychoanalysis in its theory of the qualitative factors at issue in the blocking of psychic contents—whose energy is sufficient for conscious entrance—from entering consciousness. According to analytical psychology, in addition to psychoanalysis's theoretical formulation of this qualitative factor in terms of conflicts between the so-called ego instincts and sexually charged libido, there are also qualitative factors that involve the apperceptive conflict between the two basic attitudes that govern the flow of psychic energy (introversion and extroversion) and the apperceptive conflict between the four basic functions of consciousness (thinking, feeling, sensation, and intuition).

Theory of Complexes

Analytical psychology's theory of complexes is rooted in its understanding of apperception as the psychic process by which a new content is articulated with similar, already existing contents in such a way that it becomes understood, apprehended, and clear. As such, apperception is the bridge that connects the already existing constellated contents with the new one. According to analytical psychology, apperception is either "active" or "passive." When apperception is active, the bridge between the already existing and new contents is fashioned by the association of similar contents. When the apperception is passive, the conditions are lacking for an associative bridge based upon the similarity of the already existing contents and new contents. This has as its result the dissociation between the former and latter contents, which, paradoxically, functions apperceptively to link the two. The paradoxically apperceptive apprehension of new contents that occurs in dissociation manifests these contents as symptoms.

The absence of an associative link between ego-consciousness and unconscious contents (i.e., the symptoms) in passive apperception does not preclude for analytical psychology the existence of associations with respect to the latter contents. Rather, the theory of complexes maintains that the existence of associations that refer psychic contents to other such dissociated contents and therefore *not* to the ego can be both observed and investigated. By the term *complex,* analytical psychology understands the loose association of passively apperceived contents, which lack an associative link to ego-consciousness.

Personal and Collective Unconscious

Analytical psychology understands the personal character of the associations yielded by the symptomatic (i.e., dissociated) images of the complex to provide evidence for a *personal unconscious.* Moreover, it understands the transpersonal character of those associations yielded by the symptomatic images that refer not to ego consciousness but to other images to provide evidence for a *collective unconscious.* The methodical unfolding of the transpersonal context of the associations at issue in the collective unconscious involves what analytical psychology calls the *amplification* of the associations of images that refer not to ego consciousness but to other images. Speaking of this method, Jung writes that "I adopt the method of the philologist, which is far from being free association, and apply a logical principle which is called *amplification.* It is simply the seek-

ing of parallels" (Jung, 1935/1970). Proceeding in this manner, the initial appearance of associated images is guided by *parallel material* drawn from dreams, literature, myth, religion, and art. The point of departure for the amplification of associations is always the question "How does the thing appear?" The guidance provided by the parallel material with respect to the initially appearing associated images functions to facilitate a conscious propensity to assimilate, and therefore to apperceive actively, hints or fragments of lightly toned unconscious complexes and, by associating them with parallel elements, to elaborate them in a clearly visual form.

Archetypes and Individuation

Analytical psychology unfolds a topology of the collective associative designs—termed *archetypes*—that surround the nucleus of the complex. The most basic archetypes identified by analytical psychology include the persona (the socially accepted mask assumed by the ego); the shadow (the undeveloped and therefore infantile aspects of the ego); the anima and animus (countersexual images in men and women, respectively, which apperceptively link their personal unconsciouses to the collective unconscious); and the Self (the transpersonal basis of the ego and therefore of the conscious personality). The therapeutic goal of analytical psychology is the self-conscious differentiation of ego-consciousness from the various archetypes that become constellated in the course of the life of an individual. The process of striving to realize this goal is termed *individuation.* The crucial role of the "analytical" distinction between ego-consciousness and the archetypal contents of the collective unconscious in the process of individuation is signaled in the name Jung gave to his psychology in order to distinguish it from psychoanalysis: analytical psychology.

ANDROGENS, ESTROGENS, AND BEHAVIOR

Androgens and estrogens are the primary sex hormones. Males and females produce and respond to both hormones but in different amounts, especially during prenatal life, at puberty, and in adulthood. Males have higher androgen levels and lower estrogen levels than do females. Androgens and estrogens produce physical sex differences and contribute to sex differences in psychological characteristics.

Studies In Nonhuman Mammals

Experimental studies in mammals convincingly demonstrate that androgens and estrogens affect behaviors that show sex differences. Hormones affect behavior in two ways, depending on when they are present.

In early life, when the brain is developing, hormones produce permanent changes in brain structure that affect behavior (*organizational* effects). High levels of androgen during critical developmental periods are associated with high levels of male-typical behavior (higher in level or frequency in males than in females) and low levels of female-typical behavior (higher in level or frequency in females than in males). Female rodents and primates who are treated with high doses of androgen during prenatal and neonatal periods when the brain develops show sexual behavior more typical of males than of other females. Compared to typical females, they also engage in more rough play, are more aggressive, and perform better in mazes in which males excel. Conversely, males deprived of androgen during these sensitive periods behave in ways more typical of females than of other males. Excess or reduced androgen also produce changes in the hypothalamus, which is involved in sexual behavior, and hippocampus, involved in spatial learning.

Behavior is also affected by hormones circulating in the body throughout adolescence and adulthood (*activational* effects). Studies in animals show that both sexual and nonsexual behaviors are affected by circulating hormones acting on neural activity. For example, changes in estrogen across the estrous cycle in female rats are associated with variations in motor function, perception, and learning and memory. These effects are mediated by estrogen action on

underlying brain regions, including striatum, cerebellum, and hippocampus.

Human Studies of Behavioral Effects of Androgens and Estrogens

In people, as in other species, behavior is affected by hormones in two ways: organizational changes to the brain during early development and activation of brain systems later in life.

Organizational effects of sex hormones occur during prenatal development. Sex differences in hormone concentrations are greatest during prenatal weeks 8 to 24, following the development of the genitalia. Because prenatal hormones cannot be manipulated, knowledge about human behavioral effects of hormones comes from "experiments of nature," in which hormones are altered by disease in the fetus or the mother's exposure to drugs. Studies of hormone effects on human behavior are consistent with studies in other species in suggesting that behavior is affected by androgen present early in development.

The best-studied experiment of nature is congenital adrenal hyperplasia (CAH), a genetic disease in which the fetus is exposed to high levels of androgen beginning early in gestation. If sexual differentiation of human behavior is affected by androgen present during critical periods of development (as occurs for human physical sexual differentiation and for both physical and behavioral sexual differentiation in other mammals), then females with CAH should be behaviorally more masculine and less feminine than a comparison group of females without CAH. And they are in many, but not all, ways. Compared to female controls, females with CAH are more interested in boys' toys and activities and less interested in girls' toys and activities in childhood and in adolescence, are more likely to report using physical aggression in conflict situations, have higher spatial ability, are less interested in infants and feminine appearance, and are less likely to engage in heterosexual activity and more likely to be sexually aroused by other women. However, most females with CAH have female-typical gender identity.

Findings from females with CAH have been confirmed in other ways. For example, girls exposed to masculinizing hormones because their mothers took medication during pregnancy are more likely than their unexposed sisters to report using aggression in conflict situations. Converging evidence for these special cases comes from normal individuals with typical variations in prenatal hormones: 7-year-old girls who had high testosterone in utero (determined from amniotic fluid at prenatal weeks 14 to 16) had better spatial ability than girls who had low testosterone.

The neural mechanisms mediating behavioral effects of prenatal androgen are currently not known. There are sex differences in brain structure and function, but these have not yet been well studied in relation to sex differences in behavior or to prenatal hormone exposure.

Sex hormones continue to affect behavior later in life, probably by activating neural circuits organized early in development. Androgen affects aggression, but the effect is small and bidirectional: That is, aggression itself can increase androgen. Androgen also facilitates spatial ability in a curvilinear fashion. High spatial ability is associated with relatively high androgen in females but relatively low androgen in males, but keep in mind that males on the low end of normal still have higher androgen than females on the high end of normal.

Estrogen also affects behavior later in life. Cognition changes with variations in estrogen levels resulting from the menstrual cycle, oral contraceptives, menopause, and estrogen treatment. Estrogen facilitates aspects of motor function, perhaps by modulating left-hemisphere regions involved in praxis. Estrogen also facilitates memory, so that postmenopausal women receiving estrogen supplementation have better memory than women not taking estrogen. There are associated changes in brain activity, especially in regions involved in memory, including frontal lobes and hippocampus.

Conclusions

Androgens and estrogens have powerful effects on human behavior, as they do on human physical characteristics and on behavioral and physical characteristics in nonhuman mammals. Androgens and estrogens exert some effects directly on the brain, by changing structure early in life and activity throughout life. Sex hormones may also affect behavior indirectly. For example, hormones might alter sensory thresholds, facilitating performance through improved sensation or perception, or increasing sensitivity to environmental input. Exposure to high levels of prenatal androgen may affect not only the behavior of the individual but social responses to the individual. For example, a predisposition to play with cars produced by exposure to high prenatal androgen may be increased over time by gifts received from adults. Hormones affect behavior in complex ways, as one of a set of influences, not as determinants.

ANESTHESIA

The use of anesthesia to prevent pain during surgery began in the United States in the 1800s. Surgeons turned to the nurses with whom they worked to administer the anesthetic. Anesthesia is now a recognized specialty of nursing and medicine.

Three different types of anesthesia are provided for surgical and diagnostic procedures: sedation, regional anesthesia, and general anesthesia.

Sedative drugs depress the central nervous system, causing a decrease in awareness and reducing anxiety. Some sedative drugs also cause amnesia. Sedation is most often administered prior to surgery to relieve anxiety, during unpleasant diagnostic procedures, or during regional anesthesia and surgery. Most people do not easily accept the idea of being awake during surgery. Sedation allows patients to feel as if they are asleep during a regional or local anesthetic and often prevents memory of the surgical experience.

The type and amount of sedation administered are based on the procedure being performed and the patient's physical condition, weight, and level of anxiety. Sedation necessitates close observation of the patient. Sedation and general anesthesia exist on a continuum. At some point, as more medication is administered, sedation becomes general anesthesia. Oversedation results in respiratory depression. All but the lightest sedation should be administered by an anesthetist or other health care provider skilled and experienced in airway management and the assessment of oxygenation and breathing.

Local anesthetic drugs temporarily disable the function of nerves. Regional anesthesia can be used to numb a small area of skin, a single nerve, or a large region of the body. Regional anesthesia can be used for minor procedures as well as some types of major surgery. Local anesthesia is commonly used around a wound edge before stitches are sewn in. A common nerve block is used by dentists to numb a large area of the mouth with a single injection. Epidural blocks are commonly used to anesthetize a large area of the body during labor pains or cesarean section.

Regional blocks wear off gradually; sensations such as touch, pressure, and pain, and the ability to use muscles in the anesthetized area, return to normal at different speeds. The individual will usually experience a pins-and-needles feeling before normal sensation completely returns.

General anesthetics temporarily depress brain function and result in a loss of consciousness. This produces insensibility to pain, prevents awareness, and relaxes or paralyzes voluntary muscles. A general anesthetic diminishes the brain's ability to regulate essential functions like breathing and body temperature. In addition to administering an anesthetic, the anesthetist monitors, supports, and, when necessary, controls these vital functions.

Although the initiation of general anesthesia is quick, it is a time when many critical tasks are performed. For adults, anesthetic drugs are usually injected into an intravenous line to put the patient to sleep, and then anesthetic vapor is inhaled through a breathing circuit. For infants and young children, the anesthetic vapor is often inhaled first and an intravenous line started after the child is asleep.

Many surgeries benefit from relaxation of skeletal muscles. In these cases drugs are administered that paralyze voluntary muscles. Such drugs make it impossible for patients to breathe on their own, but anesthetists are very skilled at ventilating patients. Paralysis is eliminated prior to the end of anesthesia either by allowing paralyzing drugs to wear off or by administering other drugs to counter their effects.

Awaking from general anesthesia occurs when anesthetic drugs are allowed to wear off. Anesthetists carefully control the drugs given in order that the patient emerges from general anesthesia at but not before the desired time. This takes experience and a detailed understanding of the drugs used and the patient's response to those drugs. If the patient must be left on a ventilator with a breathing tube in place, the anesthetist may take the patient to an intensive care unit asleep rather than awaking him or her from the anesthetic.

Recovery from general anesthesia continues after the patient awakens. Inhaled anesthetics are eliminated through the lungs. Small amounts are exhaled for amounts of time ranging from hours to days. Patients commonly remain amnestic for minutes or hours after awaking. Some difficulty with complex mental tasks may last several days.

In addition to administering anesthesia, anesthetists provide emergency airway management and establish circulatory access with arterial and intravenous lines. Anesthetists are skilled at placing and using artificial airway devices and ventilating patients. When patients outside the operating suite experience life-threatening breathing problems, anesthetists are often summoned to establish an airway.

Pain management is provided by physicians, surgeons, and anesthetists. Patient-controlled analgesia (PCA) allows patients to push a button that injects pain medicine into their intravenous line. The PCA pump is programmed to deliver a set dose when the patient pushes the button. A preset time interval must pass between each dose. Once the total dose given for an hour reaches the programmed limit, the PCA pump will not give any more until the next hour.

PCA allows the patient control over when pain medicine is received, which helps reduce anxiety. PCA also results in better pain relief than intermittent injections.

When a regional block is produced, whether it completely eliminates sensation and muscle tone from an area (anesthetic) or simply reduces pain sensation in that area (analgesia) depends upon the drug(s) used, as well as dose and strength. Regional anesthesia can be used for pain relief after surgery in many cases. Local anesthetics, either alone or combined with opioids, are commonly used for pain relief. When regional pain blocks affect the legs, patients are usually confined to bed. Even dilute concentrations of local anesthetic affect muscle strength enough to increase the risk of falling.

When opioids are added to a spinal or epidural anesthetic they provide pain relief that persists after the anesthetic block has stopped working. Some opioids provide hours of postoperative pain relief when used in this way. Regional analgesia often provides better pain relief than injections or PCA.

ANIMAL MODELS

When medical or psychological phenomena in animals are studied as analogues to those phenomena in humans, one is said to be using an *animal model.* Models are basic and powerful tools in biological and behavioral sciences, and this explains in part why so much research aimed at understanding human physiology, brain, and behavior is actually done with animals. The key word for understanding models is *analogy.* Use of a model is *not* a claim of identity with that being modeled. Rather, a model is a convergent set of analogies between the human phenomenon and the system that is being studied as a model for that phenomenon. Animal models are widely used in neuroscience and psychology to explore and understand new relationships and interactions among the environment, central nervous system, and behavior and to study these interrelations under simpler and more controlled conditions than can be achieved in research with humans. Animals models often allow for the discovery of causal relations not possible in research on humans.

Animal models have a long and distinguished history in studies of both normal and abnormal behavior. Life scientists (e.g., anatomists, physiologists, pharmacologists, and psychologists) broadly accept the homological and analogical bases for the use of animal models that are rooted in the evolutionary theory of Charles Darwin. Evolutionary theory projects a continuity of morphology, physiology, and the emergent emotions and "mind" from animals to humans.

At the more biological end of the continuum of behavioral neuroscience and psychological research and application, the use of animal models finds general acceptance and is largely noncontroversial. These uses include research on neural mechanisms of reflexes, motivation, emotion, learning, perception, and memory. Animal models are an established integral component of the progress of understanding in these areas. Contemporary animal models make clear that neuroscience, emotion, and behavior do not exist in a linear chain from one to the other but in a continuously interdependent interacting circle. More controversially, animal models have been and continue to be extended with success into the behavioral neuroscience of memory dysfunction in aging, problem solving and thinking, social interactions and cultural structures, drug dependency and addiction, psychopharmacology, and psychiatry.

Animal modeling is more difficult and controversial when it addresses dysfunctional behavior and psychopathology. Animal models promise an understanding of human psychopathology, not as bizarre distortions of behavior but, rather, as the consequence of lawful psychological processes whose principles and mechanisms *can* be elucidated scientifically. Ivan Pavlov was perhaps the first to argue that experimentally induced abnormal behavior in animals might teach us about human dysfunction. Behavioral scientists continued with principled analysis and research with animals in an attempt to define the potential for the emotional hazards in animals and humans that might arise "accidentally" in the course of normal learning experiences and result in the development of psychopathology. One illustrative example showed that punishment of cats' consummatory behavior resulted in persistent fears analogous to phobic neuroses but that these fears were treatable by a forced extinction procedure and concurrent feedings. This result proved particularly seminal for contemporary clinical psychologists, because it was from this that the principles for *reciprocal inhibition* were derived; reciprocal inhibition is the basis for the systematic desensitization therapy for phobias so widely used today with human patients. This example clearly demonstrates the applied value of animal models in contemporary psychopathology research.

Numerous models of human psychopathologies have been developed, some more complete and useful than others. Well-accepted and productive models include those on maternal separation, Post-Traumatic Stress Disorder, depression, alcoholism, stress and consequent psychosomatic disorders, psychosocial dwarfism, Korsokoff syndrome, and dementias of aging, among many.

Although the development of animal models is not without difficulty even at the level of systems physiology, human psychopathology can be especially difficult to model in animals. For example, schizophrenia has proved to be a challenge; part of the problem here is the plethora of human symptoms, each imperfectly associated with schizophrenia, and a lack of agreement about what should be focused upon in the analogy. Moreover, in schizophrenia, some of the

most important diagnostic criteria relate to verbal behaviors—something for which there is no easy analogue in animal behavior.

Biobehavioral dysfunctions, psychiatric disorders, and neurological diseases must continue to be studied to bring relief to literally hundreds of millions of sufferers. And, until the processes involved are better understood, scientists are deterred from classes of research with human subjects and patient populations, such as experimentation with etiologies or with therapies that involve physiological changes that are not yet understood, because they involve unwarranted risk. Animal research can help, because understanding is to be gained only through the use of living organisms.

It is particularly surprising that animal models should today be the focus of philosophical hostility in a society in which psychological problems and mental disease pose such a large threat to human well-being and for which history provides so much evidence of the scientific power and therapeutic success through the use of animal models. There are, of course, ethical considerations in the use of animals for research. The species employed must be chosen with care and knowledge of its basic physiology, the design of the research and numbers of animals necessary for a successful experimental test should be carefully determined, and the research should be performed strictly within the guidelines laid down by legal authorities and prior peer review. Scientists are obligated to demonstrate that the modeling processes are understood and that the analogies in the model developed are sound. Such models may sometimes necessarily involve the induction of distress; after all, physical and emotional distress are fundamental to the etiology of many common forms of human pathology.

Despite the conceptual, scientific, and societal challenges associated with the use of animals, the need for animal models for the advancement of physiology, neuroscience, and psychology is increasing and perhaps greater in the twenty-first century than ever before.

ANIMAL PARENTAL BEHAVIOR

Evolution requires reproduction, but for reproduction to be successful in an evolutionary sense, offspring must survive to reproduce themselves. Parental behavior is any behavior that contributes to the survival of the offspring. Among birds and mammals, species can generally be classified into *uniparental* or *biparental* depending on who is taking care of the young. Approximately 90% of bird species are biparental, meaning that both males and females participate in the care of the offspring. There is great variation in how species divide these tasks between males and females, but a general rule is that the demands of protecting and feeding the young have made biparental care highly adaptive for birds. In contrast to birds, over 90% of mammals are uniparental. Indeed, the uniquely female specialization of nursing partly defines mammals. But even among mammals, there are several monogamous species that provide biparental care. Paternal care can include all aspects of care of the young except for nursing and may involve specialized forms of grooming or defense. In many species (especially primates), *alloparenting*—that is, parental behavior from kin or even unrelated conspecifics—is an important adjunct to either uniparental or biparental care.

Much of what we know about the neurobiology of maternal care comes from studies of laboratory rats. Rats are particularly useful for such studies because nulliparous (literally "never parturient"—a female that has never given birth) adult rats do not display maternal behavior and will either avoid or attack pups. Late in the gestation period, which for a rat is 22 days, the pregnant female becomes interested in pups and begins to display full maternal behavior, including nest building, retrieving, grouping, grooming, and nursing the young. Although maternal behavior is often described as a composite, the various components may be dissociated under experimental conditions. Most research has focused on retrieval, because this behavior appears superficially to reflect maternal motivation. However, there are important aspects of maternal behavior that are not directed at pups. Not only are maternal rats more aggressive toward intruders, but they are also less fearful and markedly less responsive to stress than virgin females.

We now understand that the onset of maternal behavior in the rat depends on specific experiential, sensory, and hormonal factors, although we still do not know how these specific factors regulate each of the components of maternal care. The following conclusions can be taken from four decades of research in this area: (1) experience appears important for both the onset and the maintenance of maternal behavior, (2) sensory inputs regulate different aspects of maternal care, and (3) hormones appear more important for the onset than the maintenance of maternal behavior.

Experience

The process of giving birth to and raising young appears to result in permanent changes in behavior. Recent research has looked in great detail at individual differences in the style of mothering in rats. High licking-grooming dams spend more time grooming their pups than do low licking-grooming dams. It now appears, from cross-fostering studies, that this style of mothering is transmitted to subsequent generations, as offspring of a low licking-grooming dam

that are raised by a high licking-grooming dam will show high levels of licking and grooming toward their own pups. Thus, experiential factors that influence maternal care include not only the dam's previous experience as a mother but her own experience of being mothered as an infant.

Sensory Factors

What determines whether a female will approach or avoid a pup? Given that rats are predominantly olfactory animals, it's a reasonable bet that she responds to the odor of pups. Surprisingly, lesions of the olfactory system actually facilitate the onset of maternal behavior in virgin female rats. Presumably this is because females find pup odors aversive, so that reducing olfactory processing facilitates maternal approach, permitting ventral and oral-buccal stimulation to stimulate maternal responsiveness. In primates, visual and auditory cues (i.e., cries) may be more important than olfactory cues for stimulating maternal care.

Hormonal Factors

The onset of maternal behavior in the pregnant female rat is coincident with a sharp decrease in progesterone and an increase in estrogen and prolactin. These changes in hormones appear to be both necessary and sufficient for the onset of maternal behavior because, after pregnancy termination, estrogen facilitates and progesterone delays the onset of maternal behavior. How does estrogen prime the brain to influence behavior? It is now clear that the effects of estradiol on behavior may be due to its actions on the estrogen receptors, which are hormone-dependent transcription factors. Thus, estrogen is best considered as an early step in a cascade of cellular events that can ultimately lead to neuronal activation, recruitment of a neural system, and ultimately behavioral change.

The most important genes that are targets of estrogen action are likely to be oxytocin and prolactin and their respective receptors. Not only are these hormones important for parturition and lactation, but receptors for these hormones within the brain appear to support the onset of maternal behavior. Oxytocin given to estrogen-primed females can induce maternal care within 30 minutes. Prolactin had similar effects, although the onset takes place over days rather than minutes.

Although there is not a single brain area that represents the neuroanatomical locus of maternal behavior, lesions of the medial preoptic area (MPOA) in the most anterior aspect of the hypothalamus impair nest building and retrieval of pups, although females show no retrieval deficits for nonpup stimuli. The MPOA is not the only region involved in maternal behavior, but it is of particular interest because of its potential role in the hormonal regulation of the onset of maternal care. The MPOA is rich in estrogen and progesterone receptors as well as oxytocin and prolactin receptors. All of these receptors increase in number during gestation, and estrogen implanted directly in the MPOA facilitates the onset of pup retrieval.

In primates, including humans, it is generally assumed that hormonal factors are less important than experiential factors. In marked contrast to rats, maternal behavior in primates is generally not restricted to the postpartum period but can be observed in females of any endocrine status. Other factors such as social rank or environmental stress may be more important for primate maternal behavior.

Parental care provides an extraordinary opportunity to explore how genes and hormones influence the brain to modify behavior. In particular, the diversity of parental care, while discouraging simple generalizations across species, offers several remarkable experiments of nature, which, properly analyzed, should yield important insights into the mechanisms by which parental care evolved.

National Institute of Mental Health

ANOMIC APHASIA

Anomia refers to the inability to name things: that is, an impairment in retrieving words for things such as concrete entities (named by nouns), actions (named by verbs), or spatial relationships (named by prepositions). Anomia is a frequent part of the symptom complex that characterizes patients with *aphasia* (Goodglass & Wingfield, 1997; Tranel & Anderson, 1999), which refers to disturbances of the comprehension and formulation of verbal messages caused by acquired damage to language-related brain structures (typically in the left hemisphere). In some patients, however, anomia occurs as an isolated manifestation of acquired brain dysfunction, and in this situation the designation of *anomic aphasia* applies.

The ability to name—that is, to retrieve a particular word to designate an entity or event—is different from the ability to retrieve conceptual knowledge regarding that entity or event (Caramazza & Shelton, 1998; Gainotti, Silveri, Daniele, & Giustolisi, 1995; Pulvermüller, 1999; Tranel, 2001; Tranel, Damasio, & Damasio, 1997). Knowing what something is (its meaning, sometimes termed *semantics*) is referred to as *recognition,* and this is distinct from knowing what something is called (referred to as *naming*). In anomic aphasia, patients have lost the ability to retrieve names of things, but they have not lost the ability to recognize what things are. Hence, even when they cannot name things, anomic aphasics can usually produce accurate descriptions of those things or indicate by gestures that they have normal knowledge of things. For example, when shown a picture of a camel, the patient may say, "That is an animal that has humps on its back, lives in the desert, and can go for a long time without water." Or when shown a picture of Bill

Clinton, the patient may say, "That guy was a president, had an affair, had a southern accent." A related phenomenon occurs fairly frequently in the realm of normal experience, particularly under conditions of fatigue, distraction, or in connection with normal aging—that is, normal individuals may experience the inability to retrieve a particular name (especially proper names) even though they know perfectly well what it is that they are attempting to name (Burke, MacKay, Worthley, & Wade, 1991). This is sometimes referred to as a "tip-of-the-tongue" state (Schwartz, 1999).

Anomia can occur in connection with any sensory modality—for example, when attempting to name a picture of something, a sound, a smell, or something that is felt by the hand. Also, anomia can occur in the course of verbal discourse, as when one is speaking and suddenly cannot retrieve the name for a particular concept that is part of the intended utterance. The majority of scientific inquiries into the phenomenon of anomia, however, have focused on the visual modality and have used paradigms in which subjects are presented pictures (or actual objects) and asked to name them (Goodglass & Wingfield, 1997). This format, known as *visual confrontation naming,* is also the standard paradigm for assessing naming in patients with brain injuries. As a consequence, most of our current knowledge regarding the brain underpinnings of word retrieval (H. Damasio, Tranel, Grabowski, Adolphs, & Damasio, in press), and most theoretical accounts of this process (Dell, Schwartz, Martin, Saffran, & Gagnon, 1997; Levelt, Roelofs, & Meyer, 1999), are heavily tied to the visual modality.

The classic aphasia syndromes, including Broca's ("nonfluent") and Wernicke's ("fluent") aphasia, which include anomia as part of the symptom complex but which also involve other defects in speech and language, are associated with brain damage in the vicinity of the sylvian fissure in the left hemisphere (the left hemisphere being dominant for language in the vast majority [about 98%] of right-handed individuals and in the majority [about 70%] of left-handed individuals). Isolated defects in naming, though, which define anomic aphasia, are associated primarily with damage to structures in the left hemisphere outside the classic language regions. Specifically, anomic aphasia is most often caused by damage to the left anterior temporal lobe, to the inferior and lateral aspect of the left temporal lobe, or to the left occipitotemporal junction. Scientific investigations of patients with anomic aphasia, using modern neuroanatomical and neuropsychological techniques, have revealed a number of intriguing associations between specific brain structures and specific types of naming abilities (Caramazza & Hillis, 1991; Damasio & Tranel, 1993; H. Damasio, Grabowski, Tranel, Hichwa, & Damasio, 1996; H. Damasio et al., in press; Hart & Gordon, 1992; Hillis & Caramazza, 1995; Tranel, Adolphs, Damasio, & Damasio, 2001). Studies in normal subjects, using functional neuroimaging procedures (positron emission tomography, functional magnetic resonance imaging), have corroborated several of these findings (Chao & Martin, 2000; H. Damasio et al., 1996, in press; Grabowski et al., 2001; Grafton, Fadiga, Arbib, & Rizzolatti, 1997; Martin, Haxby, Lalonde, Wiggs, & Ungerleider, 1995; Martin, Wiggs, Ungerleider, & Haxby, 1996; Warburton et al., 1996).

The evidence from this research indicates that the retrieval of proper nouns—that is, names denoting unique entities such as persons and places—is associated with the temporal polar region in the anterior left temporal lobe. Immediately behind the temporal pole, in the inferior and lateral aspect of the temporal lobe, is a region that has been associated with the retrieval of names for animals. And further back, in the vicinity of the temporal-occipital junction, is a region that has been associated with the retrieval of names for tools. These associations may appear arbitrary or even bizarre, but there are principled accounts of why the human brain may be organized in such a fashion (H. Damasio et al., 1996, in press; Forde & Humphreys, 1999; Gainotti et al., 1995; Gordon, 1997; Humphreys & Forde, 2001; Saffran & Sholl, 1999; Tranel, Logan, Frank, & Damasio, 1997). For example, factors such as whether an entity is unique (e.g., Tom Hanks) or nonunique (e.g., a screwdriver), whether it is living (e.g., a pig) or nonliving (e.g., a hammer), whether it is manipulable (e.g., a wrench) or nonmanipulable (e.g., a giraffe), or whether it makes a distinctive sound (e.g., a rooster) or not (e.g., a thimble), are important in determining which neural structures will be used in the mapping and retrieval of knowledge for entities, including their names (H. Damasio et al., in press; Tranel, Logan, et al., 1997). Interestingly, the modality in which a stimulus is perceived may *not* make much difference: For example, retrieving the name *rooster* when confronted with a picture of a rooster, or when confronted with the characteristic sound of a rooster, appears to depend on the same left temporal lobe region (Tranel, Damasio, Eichhorn, Grabowski, Ponto, & Hichwa, 2003).

There are also intriguing distinctions between words that come from different grammatical categories, for example, nouns versus verbs. The brain regions that are important for retrieving nouns are partially separate from those that are important for retrieving verbs. As noted earlier, the retrieval of nouns is related to structures in the left temporal lobe. The retrieval of verbs, by contrast, is related to structures in the left frontal lobe, in the frontal operculum (in front of the Rolandic sulcus). And some studies have suggested that noun-verb homophones—for example, words like *hammer* or *duck,* which are used frequently as either nouns or verbs—are retrieved by the brain system that fits the context in which the word is being used: If *hammer* is being used as a noun, the temporal lobe system will be used, but if *hammer* is being used as a verb, the frontal lobe system will be used (Tranel, 2001). Again, such dissociations may appear rather curious on the surface, but there are compelling explanations of why the brain has organized knowledge in different regions to subserve words from different grammatical categories (Caramazza &

Hillis, 1991; Damasio & Tranel, 1993; Kemmerer, Tranel, & Barrash, 2001; Tranel et al., 2001).

Pure forms of anomic aphasia—that is, severe naming impairments unaccompanied by other speech or linguistic deficits—are relatively rare, occurring far less frequently than most of the so-called classic aphasia syndromes. Nonetheless, patients with anomic aphasia have provided a unique opportunity to learn how the brain operates the processes associated with word retrieval, and how different brain structures are specialized for different types of words and different categories of entities. Thus, while anomic aphasia is important as a clinical disorder, its particular interest lies in the realm of scientific study of how the human brain operates language processes. This, in turn, can help inform rehabilitation efforts aimed at patients with acquired disturbances of naming.

ANOREXIA NERVOSA

Definition and Clinical Descriptions

The disorder of anorexia nervosa (AN) is defined by four major criteria.

1. Refusal to maintain body weight at a minimally normal weight for age and height.
2. An intense fear of gaining weight. This fear, present even in an emaciated condition, may be denied, but it is demonstrated by an intense preoccupation with thoughts of food, irrational worries about gaining weight, and rigorous exercising programs, with severe restriction of total food intake in order to prevent weight gain.
3. A disturbance of body conceptualization. Parts of the body such as the thighs and abdomen are experienced as being excessively large; evaluation of the self is mainly in terms of body weight and shape; and the denial of illness or the underweight condition is a hallmark symptom of this disorder.
4. Amenorrhea or cessation of menstrual cycles.

There are two subtypes of AN: the restrictor type (AN-R) and the binge-purge type (AN-BP). The restrictors lose weight by restricting food intake and exercising; the binge-purge type engages in binge eating, purging behavior (such as self-induced vomiting), laxative abuse, and diuretic abuse.

Impulsive behaviors including stealing, drug abuse, suicide attempts, self-mutilations, and mood lability are more prevalent in AN-BP than in AN-R. The AN-BP types also have a higher prevalence of premorbid obesity, familial obesity, and debilitating personality traits (Halmi, 1999).

Most of the physiological and metabolic changes in AN are secondary to the starvation state or purging behavior. These changes revert to normal with nutritional rehabilitation and the cessation of purging behavior. Hypokalemic alkalosis occurs with purging. These patients may have hypokalemia and physical symptoms of weakness, lethargy, and cardiac arrhythmias, which may result in sudden cardiac arrest. Persistent vomiting causes severe erosion of the enamel of teeth, with consequent loss of teeth, and produces parotid gland enlargement (Halmi, 1999). Chronic food restriction produces osteoporosis and fractures.

Epidemiology

There was a consistent increase in the incidence of AN over the period from 1931 to 1986 in industrialized countries (Hoek, 1993). A study conducted in northeastern Scotland (Eagles et al., 1995) showed that between 1965 and 1991 there was almost a sixfold increase in the incidence of anorexia (from 3 in 100,000 to 17 in 100,000 cases). The male-female ratio for eating disorders lies consistently between 1/10 and 1/20 (Hoek, 1993).

AN is rare in non-Western, poorly industrialized countries (Lee, Leung, & Lee, 1996). Individuals and groups who are exposed to the ideal of a slender body type seem to be a risk for developing an eating disorder (Crago, Schisslak, & Estes, 1996). A review of eight studies in the 1980s (Gard & Freeman, 1996) failed to support a higher social economic class prevalence in AN.

Etiology and Risk Factors

AN is best conceptualized by a multidimensional model that emphasizes the interaction of biological, psychological, and cultural factors. Within each of these areas, research has identified factors that predispose, precipitate, or maintain the eating disorder.

Genetic Factors

In a series of 67 twin probands, the concordance for restricting AN was markedly higher for monozygotic twins, 66%, than for dizygotic, 0%. A familial aggregation of AN and Bulimia Nervosa is present in AN probands (Treasure & Holland, 1989).

A genomewide linkage analysis of 192 families with one AN member and another with any related eating disorder identified in the *Diagnostic and Statistic Manual of Mental Disorders* (fourth edition) showed a modest linkage on chromosome 4. When a subset of 37 families containing 2 with restricting AN was analyzed, a more robust linkage was found on chromosome 1p (Devlin et al., 2002; Grice et al., 2002).

A vulnerability for destabilization of the endocrine and metabolic mechanisms affecting eating behavior may cause the full-blown eating disorder under stresses such as severe dieting. Neurotransmitter serotonin pathways modulate feeding and inhibitory behaviors. There is evidence of aberrations in this neurotransmitter system in anorectic patients.

Because AN predominately starts during puberty (there is a bimodal peak for age onset at ages 14–15 and age 18), Crisp (1970) developed the hypothesis that AN reflects an attempt to cope with maturational problems through the mechanism of avoidance of biological maturity.

A genetic predisposition to develop AN could be a particular personality type. There is evidence that a rigid, inhibited, and perfectionistic personality may be at risk for developing AN-R (Halmi, 1999).

Two behavior variables, obsessionality and drive for thinness, showed high and concordant values in a cluster of AN pairs. These variables in the AN pairs showed suggestive linkages on chromosome 1, 2, and 13 (Devlin et al., 2002).

Family Functioning

Studies of anorectic families show they have more rigidity in their family organization, less clear interpersonal bound-

aries, and a tendency to avoid open discussions of disagreements among themselves compared with control families (Humphrey, 1988).

Stressful Events

Stressful life events may be a risk factor for developing AN. Studies investigating the relationship between sexual abuse and eating disorders have produced highly discrepant results (Connors & Morse, 1993). A low rate of sexual abuse has been reported among anorectic restrictors relative to either bulimic anorectics or to normal-weight bulimics (Waller, Halek, & Crisp, 1993).

Normative developmental events, such as the onset of puberty, departure from home, or a change of school, can precipitate an eating disorder. Adverse life events, such as the death of a close relative, the breakup of a relationship, or illness, may also precipitate an eating disorder (Tobin et al., 1995).

Course of Illness

Long-term follow-up research indicates that about one fourth of those with AN recover from the disorder, one fourth stay chronically ill with no improvement, and about half have partial improvement. Most of the latter have bulimic behaviors. Mortality rates at 10 years are 6.6% and at 30 years are 18% to 20% after presentation for treatment (Eckert et al., 1995).

Patients with an earlier onset, between ages 13 and 18, recover from the disorder more quickly. Most studies have found purging behavior to be a poor outcome predictor.

Treatment

There are few outpatient controlled treatment studies of AN. Open studies have indicated that a multifaceted treatment approach is the most effective. This includes medical management, psycho-education, and individual therapy utilizing both cognitive and behavioral therapy principles. Controlled studies have shown that children under the age of 18 do better if they have family therapy (Russell et al., 1987). Nutritional counseling and pharmacological intervention can also be useful components of the treatment plan.

Treatment levels range from a specialized eating disorder inpatient unit to a partial hospitalization or day program to outpatient care, depending on the weight, medical status, and other psychiatric comorbidity of the patient. Medical management usually requires weight restoration, nutritional rehabilitation, rehydration, and correction of serum electrolytes for hospitalized patients. Cyproheptadine in high doses can facilitate weight gain in AN-R, and serotonin reuptake inhibitors may be effective in preventing relapse (Halmi, 1999).

Cognitive and behavioral therapy principles can be applied with both inpatients and outpatients. Behavioral therapy is effective for inducing weight gain. Cognitive therapy techniques for AN have been extensively described (Kleifield, Wagner, & Halmi, 1996). These include the monitoring of food intake, feelings and emotions, binge/purge behaviors, and problems in interpersonal relationships. Cognitive therapy also uses the techniques of cognitive restructuring and problem solving.

Family Therapy

A family analysis should be done on all AN patients who are living with their families and a decision made as to what type of family therapy or counseling is advisable. Most clinicians find it necessary to combine individual therapy with some sort of family counseling.

At the present time no treatment modality can predict recovery in a specific AN patient.

ANTABUSE (Disulfiram) AND OTHER ANTI-ALCOHOLISM DRUGS

Antabuse (disulfiram), a drug used as a supplementary therapy for alcoholism, was originally used in the manufacture of rubber. When the chemical got into the air in one factory and settled on the workers' skin, many developed dermatitis (Schwartz & Tulipan, 1933). If they inhaled the disulfiram, they discovered that they could no longer tolerate alcohol. Beginning in the 1940s, therapists tried using the drug as a therapy for alcoholism, on the theory that alcoholics would learn to avoid alcohol because of its now unpleasant aftereffects.

Antabuse alters the metabolism of alcohol. Ethanol (ethyl alcohol) is metabolized in the liver by the enzyme alcohol dehydrogenase into acetaldehyde, a toxic chemical. Acetaldehyde is then metabolized by the enzyme aldehyde dehydrogenase (also known as aldehyde NAD-oxidoreductase) into acetate (acetic acid), which is a source of energy. Antabuse and a similar drug, Temposil (calcium carbimide), bind to the copper ion of acetaldehyde dehydrogenase and thereby inactivate it. Consequently, after someone drinks ethanol, it is converted as usual to aldehyde, but the aldehyde then accumulates instead of being converted to acetate. Symptoms of acetaldehyde accumulation include flushing of the face, increased heart rate, nausea and vomiting, headache, abdominal pain, and labored breathing. People using Antabuse are advised to take a 200 to 500 mg pill daily and warned that drinking alcohol within a day or two after taking a pill can cause severe illness. They need to avoid even using shampoos containing alcohol, because of the danger of skin rashes. Giving someone Antabuse without his or her knowledge would be unethical and hazardous because of the likelihood that the person would unknowingly drink enough alcohol to become severely ill.

For genetic reasons, some people produce lower than average amounts of the enzyme aldehyde dehydrogenase. Drinking alcohol produces for them symptoms similar to, although generally milder than, those associated with Antabuse. About half of Chinese and Japanese people have low amounts of this enzyme, and partly because of this lack alcohol abuse has historically been less common in China and Japan than in most other countries (Tu & Israel, 1995).

Many sources state that Antabuse is not significantly more effective than a placebo, citing a study by Fuller and Roth (1979). That criticism is misleading, however. The study included one group who were correctly told that they were taking a placebo and one who were given placebos but intentionally misinformed that they were taking Antabuse. The group taking Antabuse and the placebo group who believed they were taking Antabuse fared similarly: In both cases about one fourth of the individuals abstained completely throughout the year, whereas the others quit taking the drug and resumed drinking. Both of these groups did far better than the group who knew they were taking a placebo, who unsurprisingly continued drinking heavily. In other words, taking Antabuse, or believing one is taking Antabuse, is an effective deterrent to drinking and a useful adjunct to a decision not to drink. The pharmacological properties of Antabuse were irrelevant in this study, simply because those alcoholics who wished to resume drinking stopped taking the pill.

One review of 24 studies concluded that Antabuse on the average decreases the number of drinking days and the total consumption of alcohol but does not significantly increase the probability of remaining abstinent over the long term (Hughes & Cook, 1997). The problem in evaluating the effectiveness of Antabuse is the high frequency of noncompliance among participants in most of the research. Many alcoholics, even if they begin with good intentions, quit taking the pills or take them only sporadically. When therapists have taken measures to increase compliance, such as having someone's friend or relative supervise the daily pill-taking, the results have been more encouraging (Azrin, Sisson, Meyers, & Godley, 1982). A review of just those studies that maintained enough supervision to assure compliance concluded that supervised Antabuse is statistically and clinically effective in preventing relapse of al-

coholism (Brewer, Meyers, & Johnsen, 2000). One possible way to improve compliance is to develop an implant that would provide sustained release in controlled quantities. However, effective and reliable implants have not yet been developed (Hughes & Cook, 1997).

The other drug approved in the United States for use against alcoholism is naltrexone, which blocks opioid receptors in the brain. Naltrexone is an antidote for excessive heroin use and helps decrease heroin cravings. Alcohol indirectly activates opioid pathways, and naltrexone decreases cravings for alcohol (Swift, 1999). The drug acamprosate (Campral) is sometimes used against alcohol in Europe, but as of 2002 it was not available in the United States. Acamprosate increases activity at glutamate type NMDA receptors in the nucleus accumbens, in contrast to alcohol, which decreases glutamate transmission (Berton, Francesconi, Madamba, Zieglgansberger, & Siggins, 1998). Acamprosate has shown promise in helping abstaining alcoholics to avoid relapse, with an effectiveness approximately equal to that of naltrexone (Kranzier & Van Kirk, 2001). Another drug used in Europe is tiapride, which blocks dopamine receptors (Swift, 1999). Dopamine activity is critical for nearly all types of reinforcement, so although blocking it may have potential for decreasing alcoholism, it runs the risk of decreasing other motivations as well.

For all of these drugs used against alcoholism, the problem is compliance. Many alcoholics have mixed feelings about quitting alcohol and decreasing their own cravings and at various times many of them quit taking the drugs. In short, any of these drugs can be a useful supplement to other forms of treatment, but only under conditions of adequate supervision to assure compliance.

ANTHROPOLOGY

The Nature of Anthropology as a Discipline

Anthropology is an outgrowth of the sixteenth-, seventeenth-, and eighteenth-century European discoveries of the remains of ancient civilizations and fossil ancestors as well as Europeans' encounters with contemporary cultures that differed greatly from those of Europe. The need to explain, understand, and deal with these discoveries as a means of better understanding their own cultures gave rise to anthropology as an academic and museum discipline.

It was not until the late nineteenth and early twentieth centuries, however, that a coherent intellectual structure emerged for the discipline. In the United States Franz Boas, of Columbia University, helped combine four subfields into what we now see in most major U.S. university departments of anthropology: cultural anthropology, archaeology, anthropological linguistics, and physical (biological) anthropology. Combined research in these four subfields has achieved a broad coverage of human biological and cultural evolution in its study of the world's cultures, past and present—the most distinguishing feature of anthropology. The concept of culture has become the unifying theoretical framework that allows the subdisciplines of the field to interact in research and teaching.

Cultural anthropology deals with the description and analysis of the forms and styles of human social life. One subdiscipline of anthropology, ethnography, systematically describes societies and cultures. Another subdiscipline, ethnology, is the closely related theoretical comparison of these descriptions that provides the basis for broad-based cultural generalizations.

Archaeology and its systematic excavation of the interred remains of the past reveal sequences of social and cultural adaptations and evolution under diverse natural and cultural conditions. Archaeology makes substantial contributions to the study of man in its quest to understand prehistory and in its investigation of the full cultural record of mankind.

Anthropological linguistics provides yet another essential perspective with its investigation of world languages. A major objective of this field is reconstructing historical

changes that have led to the formation of contemporary languages and families of languages. In a more fundamental sense, anthropological linguistics is concerned with the nature of language and its functions in human and prehuman cultures. Anthropological linguistics is also concerned with the relationships between the evolution of language and the evolution of cultures. Finally, anthropological linguistics is essential for the cultural anthropologist seeking to understand and to write heretofore unwritten languages.

The subfield of physical (biological) anthropology concentrates on man's prehuman origins and takes into account both genetically and culturally determined aspects of human beings. Physical anthropology seeks to identify the processes of human evolution by studying the fossil remains of ancient human and prehuman species and by describing and analyzing the distribution of hereditary variations among contemporary populations increasingly by means of genetic research.

The Relevance of Anthropology as a Discipline

Anthropology does not achieve its general and fundamental significance by organizing the data of other disciplines or by synthesizing higher-level theories from the other disciplines' concepts and principles. Anthropologists are interested in the facts and theories of other disciplines that apply to the study of man. Certainly there are many collaborative efforts and fruitful exchanges between anthropologists and biologists, psychologists, sociologists, social psychologists, geologists, historians, and economists, as well as scholars in the humanities. It should also be noted that as research and publications accumulate in each of the four subfields of anthropology, fewer and fewer anthropologists are masters of the entire discipline. In fact, anthropologists increasingly find themselves working not only with fellow anthropologists but also with members of entirely different scientific and humanistic disciplines. For example, cultural anthropologists interested in the relationships between cultural practices and the natural environment must study the principles of ecology. Physical anthropologists studying the relationships between human and protohuman fossils may, because of the importance of teeth in the fossil record, become more familiar with dentistry journals than with journals devoted to ethnography or linguistics. Cultural anthropologists who focus on the relationships between culture and an individual's personality are sometimes more at home professionally with psychologists than with archaeologists in their own university departments. Likewise, anthropology makes great contributions to museums, and many anthropologists spend their careers as museologists. In general it may be said that the working links between anthropological specialties and other disciplines are quite pragmatic. Ongoing specialization requires branching out in many directions in response to research opportunities, scholarly interests, and new discoveries and research techniques.

An important feature of anthropology as a discipline is that its scope is panhuman in its theoretical foundation. It is systematically and uncompromisingly diachronic and comparative in its insistence that the proper study of man can only be undertaken successfully through a general study of mankind. The anthropological impulse is, first and foremost, to insist that conclusions based upon the study of one particular human group or civilization be checked against the evidence gleaned from other groups under both similar and different conditions. In this way the relevance of anthropology transcends the interests of American, Western, or any other culture. In anthropological perspective, all civilizations are particular, local, and evanescent; thus, anthropology opposes the ethnocentrism of those who would have themselves and none other represent humanity, stand at the pinnacle of progress, or be chosen by God or history to fashion the world in their own image.

Because of its diachronic and comparative perspectives anthropology holds the key to answering the recurring fundamental questions of contemporary relevance to humanity. It lies peculiarly within the province of anthropology to contextualize the place of man's animal heritage in modern society, to define what is distinctively human about humans, and to differentiate between cultural and noncultural reasons for conditions such as competition, conflict, and war.

Anthropological facts and concepts are essential to an understanding of the origins of social inequality, racism, exploitation, poverty, underdevelopment, and other human problems. Of decisive importance to the entire anthropological enterprise is the question of the nature and significance of human racial variation. Because of its combination of biological, archaeological, linguistic, and cultural perspectives, general anthropology is uniquely suited to address this problem.

In addition to its basic research mission, anthropology has become an applied science with applications in most areas of contemporary life. Techniques of applied anthropology may now be seen in problem-solving activities across the spectrum of virtually all cultural and biological domains. Applied anthropologists in the United States alone number in the thousands and are employed as professionals and scientists in government, business, the military, health, education, and various other fields. It is now predicted that half of all graduating doctorates in anthropology will pursue nonacademic careers.

Underlying all of anthropology's other contributions to the sciences and humanities is its abiding search for the causes of social and cultural differences and similarities in the family of man. This enduring quest to understand both the biological and cultural nature of mankind in a diachronic and comparative framework continues to distinguish anthropology as an essential and vital component of a sound education for the modern world.

ANTIDEPRESSANT MEDICATIONS

Medications effective in reducing the symptoms of major depression are called *antidepressants.* The Food and Drug Administration requires controlled, double-blind studies showing safety and efficacy before approving an antidepressant medication to be available in the United States.

Major Depressive Disorder is characterized by sadness and an inability to experience pleasure. Associated symptoms include decreased self-esteem, feelings of hopelessness and worthlessness, excessive guilt, and difficulty with concentration, memory, and decision making. Anxiety manifested as fear, nervousness, or excessive worry is also common in depression. A greater focus on bodily sensations can result in somatic symptoms. Sleep difficulties marked by reduced or excessive sleep, and a change in appetite with consequent weight loss or gain, are also present. Suicidal ideas can lead to suicidal attempts with the potential to succeed. The diagnosis of major depression requires these symptoms to be present fairly continuously for a minimum of 2 weeks and to be associated with significant distress or impairment in role function.

There are different forms of major depression, including one seen in bipolar disorder in which individuals have episodes of not only depression but also forms of mania; melancholia, characterized by symptoms like a distinct quality of sadness, inability to experience pleasure, and early morning awakening; and atypical depression, which is more responsive to environmental events and associated with an increase in appetite and need for sleep. The presence of depressive symptoms that fall below the threshold of criteria for major depression is called by various names: *dysthymia* (which is a chronic lower-grade depression and still impairing), depressive symptoms in response to negative life events, and minor depression.

Depression is believed to arise from a combination of genetic vulnerabilities and environmental factors. Traumatic experiences, particularly if they occur in childhood, are a potential environmental risk factor for the development of depression.

Medications to treat depression are classified based on their chemical structure and pharmacological effect. Three major classes of antidepressants are available in the United States. These are the tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), and selective serotonin reuptake inhibitors (SSRIs). The initial effects of these medications in the brain are primarily on two chemical messengers called neurotransmitters—norepinephrine and serotonin. The TCAs have a prominent effect in blocking the recycling of norepinephrine. Commonly used TCAs included imipramine (trade name Tofranil), amitryptaline (Elavil), doxepin (Sinequan), desipramine (Norpramin), and nortriptyline (Pamelor and Aventyl). One TCA, clomipramine (Anafranil), also powerfully blocks the recycling of serotonin. The MAOIs inhibit an enzyme, monoamine oxidase, that is important in the physiological breakdown of norepinephrine and serotonin. Commonly used MAOIs include phenelzine (Nardil) and tranylcypramine (Parnate). The SSRIs selectively block the recycling of serotonin. These include fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), and citalopram (Celexa).

Some antidepressant medications do not fall easily into the above groups. Buproprion (Wellbutrin) is believed to block the recycling of norepinephrine as well as another neurotransmitter, dopamine. Venlafaxine (Effexor) blocks the recycling of both serotonin and norepinephrine. Nefazodone (Serzone) blocks the recycling of serotonin and additionally a specific serotonin receptor. Mirtazapine (Remeron) impacts a specific norepinephrine receptor on the serotonin cell, increasing its firing rate while simultaneously blocking some serotonin receptors.

The benefits of antidepressant medications are rarely immediate but accrue gradually over several weeks. They appear to modulate primary negative emotional responses like anxiety in structures like the amygdala, such that cognitive and executive choices are more available to drive behavioral responses. The maximum benefit may not plateau until several months. The initial effect of antidepressants begins a cascade of events in critical neurons that are ultimately believed to alter the expression of specific genes. Recent studies suggest that antidepressants enhance the activity of neurotropic agents that impact neurogenesis. This process is gradual, thus the delay in obtaining the full benefits of antidepressant medications.

In addition to their therapeutic benefits, antidepressant medications also have unwanted effects. These side effects can be explained by their pharmacological effects in areas other than the sites involved in their beneficial effects, or by their effects on other receptors. The TCAs appear to have the largest number of such unwanted effects, including potential effects on the electrical conduction system in the heart. This effect makes them particularly dangerous if taken in overdose. The TCAs' effects on the cholinergic, histaminergic, and alpha-1 adrenergic receptors mediate the majority of their adverse effects. MAOIs indiscriminately inhibit the monoamine oxidase enzyme, and as a result they have the potential to interact with other specific medications or with food substances like cheese. Such an interaction may increase blood pressure, which, if high enough, can cause strokes and even death. The newer antidepressants like the SSRIs, because of their greater selectivity in their pharmacological actions, are less likely to cause serious side effects. However, with the exception of buproprion, nefazodone, and mirtazapine, their potential for causing sexual side effects seems to be greater.

Antidepressants have been increasingly recognized as being effective in a variety of other conditions other than major depression. These include dysthymia and the anxiety disorders like Generalized Anxiety Disorder, Panic Disorder, Obsessive-Compulsive Disorder, Post-Traumatic Stress Disorder, and Social Anxiety Disorder.

In a general group of patients with major depression,

roughly 10–20% are intolerant to the first antidepressant tried. Of the remaining, roughly half are able to tolerate the medications without any significant side effects. Side effects, when they occur, may fade as the individual gets used to the medication. Occasionally, side effects develop gradually over time.

An adequate trial of an antidepressant requires a minimum of a month or two on an adequate dose. Roughly two thirds of the individuals will obtain at least a 50% reduction in the severity of their depressive symptoms. One quarter to one third may achieve remission, which is considered a full or close to a full level of response. Those who fail to respond might respond to either switching the medication to another class of antidepressants or augmenting the first antidepressant with one of several choices. Individuals who fail to respond to antidepressant medications may respond to electroconvulsive therapy, believed to be the most powerful treatment available for major depression.

ANTISOCIAL PERSONALITY DISORDER

Antisocial Personality Disorder (ASP) is characterized by a pattern of socially irresponsible, exploitative, and guiltless behavior that begins in early childhood or early adolescence. Typical behaviors include criminality and failure to conform to the law, failure to sustain consistent employment, manipulation of others for personal gain, frequent deception of others, and a lack of empathy for others.

Antisocial behavior has been described throughout recorded history, yet formal descriptions date only to the early nineteenth century. Philippe Pinel, founding father of modern psychiatry, used the term *manie sans delire* to describe persons who were not insane but had irrational outbursts of rage and violence. In the late nineteenth century, German psychiatrists coined the term *psychopathy* to describe a broad range of deviant behaviors and eccentricities. The term was later popularized by the American psychiatrist Hervey Cleckley in the now-classic *Mask of Sanity,* originally published in 1941 (1941/1976). The term *sociopathic personality disturbance* was introduced in the first edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-I*), published in 1952, and was replaced by *Antisocial Personality Disorder* in 1968 in the second edition of the *DSM,* a term whose use has continued to the present in the fourth edition of the *DSM.* The term *antisocial* implies that the disturbance is directed against society.

Clinical Findings

Antisocials typically report a history of childhood behavior problems, such as fights with peers, conflicts with adults, lying, cheating, stealing, vandalism, fire setting, running away from home, and cruelty to animals or other children. As the antisocial youth achieves adult status, other problems develop that reflect a lack of age-appropriate responsibilities, such as uneven job performance, being undependable, changing jobs frequently, and being fired. Criminal behavior, pathological lying, and the use of aliases are also characteristic.

Survey data show that from 2% to 4% of men and 0.5% to 1% women in the United States are antisocial. The percentages are much higher in prisons and psychiatric hospitals and clinics, and among homeless and alcohol- and drug-addicted persons.

Natural History

The disorder is chronic, although it tends to be worse early in its course, and patients tend to improve with advancing age. In a 30-year follow-up study, Robins (1966) found that of 82 antisocial subjects, 12% were in remission, and another 20% were deemed improved; the remaining subjects were considered as disturbed, or more disturbed than at the study onset. The median age for improvement was 35 years.

Psychiatric comorbidity is common, and many antisocial persons suffer from an alcohol or drug use disorder, a mood disorder, an anxiety disorder, or an attention-deficit disorder (ADD). Sexual dysfunction, paraphilias, other personality disorders (e.g., borderline personality), and impulse control disorders (e.g., pathological gambling) are also frequent. Risk for death from suicide or homicide is elevated.

Etiology

ASP may be genetically transmitted to some extent. Family studies show that nearly one fifth of first-degree relatives of antisocials are themselves antisocials. ASP is more commonly found in both identical twins than among nonidentical twins, and offspring of an antisocial parent who are adopted in childhood are more likely to develop ASP than adoptees without an antisocial parent.

Chronic nervous system underarousal is thought by some researchers to underlie ASP. This theory is supported by evidence that antisocials have low resting pulse rates, low skin conductance, and an increased amplitude on event-related potentials.

The central nervous system (CNS) neurotransmitter serotonin has been linked with impulsive and aggressive behavior. Low levels of cerebrospinal fluid 5-hydroxyindolacetic acid (5-HIAA)—a metabolite of serotonin—have been found in men who killed with unusual cruelty or committed arson and in newborns with a family history of ASP.

Other evidence points toward abnormal CNS functioning in ASP. Positron emission tomography scans in a group of criminals who had either committed or attempted murder showed abnormal function in the prefrontal cortex. In another study, which used structural magnetic resonance imaging, antisocial men had a reduction in prefrontal gray matter volume.

The social and home environment also contributes to the development of antisocial behavior. Parents of troubled children show a high level of antisocial behavior themselves, and their homes are frequently broken by domestic abuse, divorce, separation, or the absence of a parent. Antisocial persons often have a history of childhood abuse.

Managing ASP

Antisocial patients who seek help can be evaluated on an outpatient basis. A careful psychiatric interview supplemented by information from informants is the best way to assess ASP, because there are no diagnostic tests. Cognitive therapy has recently been used to treat ASP and involves helping patients to recognize and correct situations in which their distorted beliefs and attitudes interfere with their functioning. Antisocial patients can be very difficult to treat because they typically blame others for their problems, have a low tolerance for frustration, are impulsive, and rarely form trusting relationships.

Several drugs have been shown to reduce aggression, the chief problem of many antisocials, but no medications are routinely used or specifically approved for the treatment of ASP. Lithium carbonate and phenytoin have both been found to reduce anger, threatening behavior, and assaultiveness among prisoners. Other drugs used have been used to treat aggression primarily in brain-injured or mentally retarded patients, including carbamazepine, valproate, propranolol, buspirone, trazodone, and the antipsychotics. Medication targeted at comorbid major depression, anxiety disorders, or ADD may help to reduce antisocial behavior. Antisocial substance abusers who stop abusing are less likely to engage in antisocial or criminal behaviors, and they have fewer family conflicts and emotional problems.

Antisocials with spouses and families may benefit from marriage and family counseling. Bringing family members into the counseling process may help antisocial patients recognize the impact of their disorder on others. Therapists who specialize in family counseling may be helpful in addressing antisocials trouble in maintaining enduring attachments to their spouse or partner, their inability to be effective parents, their problems with honesty and responsibility, and the anger and hostility that can lead to domestic violence.

Prevention of ASP

Preventive measures should focus on teaching children how to recognize and reject bad behavior, how to make acceptable judgments between right and wrong, and how to connect actions with consequences. Parents of troubled children may need special training to show them how to identify and correct misbehavior as it occurs and how to steer their children away from negative influences like delinquent peers. Antiviolence programs such as those offered in some public schools may help children find alternatives to lashing out.

ANXIETY

Introduction

One of the best definitions of anxiety, put forth over fifteen years ago by Kandel (1983), remains highly apt and appropriate today: "Anxiety is a normal inborn response either to threat—to one's person, attitudes, or self-esteem—or to the absence of people or objects that assure and signify safety" (p. 1277).

Anxiety is an emotion and state of mind characterized by aversive cognitive (apprehensive expectation of negative experience or consequences), physiologic (autonomic hyperarousal with multiple somatic symptoms), and behavioral (hypervigilance, avoidance, paralysis of action) components. Its relationship to fear states in animals is ambiguous. Fear is an adaptive response to a clear-cut, external threat; anxiety is excessive or inappropriate in relation to the stimulus and often extends well beyond the provoking situation (i.e., the cognitive aspect of anxious anticipation and uncertainty about the future). This distinction may simply reflect the highly complex and more developed human brain,

whose frontal lobes allow for a degree of planning and rehearsal of future events not possible in animals, along with a capacity for symbolism that facilitates multiple higher-order contextual associations with negative affect. Although a certain amount of anxiety, analogous to fear, is adaptive in helping the organism prepare a response to a demanding situation, excess anxiety is maladaptive, characterizes a number of the clinical anxiety disorders, and also occurs as a significant symptom complex in other psychiatric disorders, most notably depression.

Psychological Approaches

Until recently, theories of anxiety were largely psychological (Craig, Brown, & Baum 1995). Psychoanalysis emphasized the importance of early childhood experience as it was stored in the brain or mind. Internal conflicts and/or damaged self-esteem based on these memories and recollections served as a cognitive stimulus for anxiety.

Learning and behavior theorists conceptualized anxiety as a response to a specific environmental stimulus that could be maintained by reinforcing consequences, and they used this understanding of the immediate triggers and consequences of anxiety to design specific treatment interventions. This strictly behavioral approach was most applicable to the treatment of phobias (i.e., excessively fearful responses to concrete environmental situations and cues). Later theorists added a cognitive element to these concepts, focusing on the role of internal cognitive stimuli as potential triggers or reinforcing factors. This development moved discussion more into the realm of psychoanalysts, and at the same time this cognitive focus allowed learning theorists to bridge the gap between the more behaviorally concrete animal fear and the more human (i.e., cognitive) element in anxiety.

Neuroscience Perspectives

Recent developments in understanding the basic neurobiology of anxiety have allowed theorists to combine a neuroscience and behavioral/learning perspective to understand the role of both nature and nurture in determining the anxiety response. In this conceptualization, both external and internal (i.e., cognitive) environments play important roles in modulating activity in key brain areas that control the processing of environmental signals and the propensity for an anxiety response. This dual contribution is consistent with the equal and important role of both medication and psychotherapeutic approaches to the treatment of the various anxiety disorders.

The amygdala is an almond-shaped brain structure below the cerebral cortex and deep inside the temporal lobes. It serves as a central integrative brain center that coordinates both stimulus processing and anxiety response generation (LeDoux, 1996). This coordination is made possible by a rich set of reciprocal connections to higher cortical centers that process and compare multiple sensory and cognitive signals and to lower brain-stem centers that regulate blood pressure, pulse, respiration, digestion, and other arousal-related functions. In animals, lesioning the amygdala prevents acquisition of a conditioned emotional response (so that animals cannot learn the association between, for example, an electric shock and a light signal). Thus, the amygdala is a key brain structure modulating the ability to learn an association between various environmental contexts and danger, anxiety, or apprehension.

Many studies of the anxiety and stress response have implicated key hormones and neurotransmitters. Prominent among these are corticotropin-releasing hormone (CRH), which modulates adrenal cortisol response; norepinephrine, which controls the ratio of signal to noise, thereby alerting the organism to the relevance of certain stimuli; and serotonin, which plays a key "braking" role in controlling sensory input to the amygdala as well as modulating anxiety responsivity. Brain norepinephrine synergizes with CRH in activating arousal of the peripheral sympathetic nervous system and central nervous system, the amygdala plays a key role in orchestrating this response, and these hormones may provide feedback to the amygdala that potentiates the anxiety response.

It is of some interest that the responsivity of a number of these stress hormones has been linked to developmental experience by an elegant series of studies. These studies show that early adverse life experiences appear to set thresholds for activity of these various stress response systems. Separation and loss, hardship, and abuse serve to increase the individual's tendency for hormone/neurotransimitter-related hyperarousal (Coplan et al., 1998). These findings are consistent with studies showing an increased rate of early adverse life experiences, especially separation and loss, in patients with various pathologic anxiety disorders.

There are significant genetic contributions to anxiety (Plomin, DeFries, McClearn, & Rutter, 1997). Twin studies have shown heritability in children for a dimension of fearfulness called *behavioral inhibition,* as well as shyness, and in adults for the personality characteristics of neuroticism. Behavioral inhibition before 1 year of age is associated with an increased cortisol and heart rate response (Kagan, 1997) consistent with the setting of lower thresholds for stress response system activation previously noted. However, twin studies also show a significant role for the environment (e.g., a proportion of behaviorally inhibited infants improve by age seven, whereas some noninhibited infants acquire this response at age seven).

In the context of this neurobiologic system that modulates anxiety response, the dual roles of medication and psychotherapy can be readily appreciated. Antidepressant medications (which also have potent anti-anxiety effects) work on neurotransmitter systems in lower brain-stem centers that control input and outflow from the amygdala. More purely anti-anxiety medications (e.g., benzodiazepine tranquilizers) work in the amygdala itself, directly damp-

ening certain inputs and perhaps affecting output. In contrast, psychotherapy probably works at higher cortical centers, which will affect sensory input to the amygdala as well as modifying amygdala processing itself via the reciprocal connections, thereby affecting the proclivity to generate an anxiety response and the likelihood that this response can be extinguished with new experience and learning. The greater effectiveness of combined treatment with both modalities, often observed in studies of anxious patients, can be readily appreciated from this point of view.

ANXIETY DISORDERS

Anxiety disorders are among the most prevalent of psychological disorders, affecting up to 20% of the population. The key features shared by the anxiety disorders include excessive or unrealistic fear and anxiety, avoidance of feared objects and situations, and excessive attempts to reduce discomfort or to protect oneself from potential threat. In addition, for an anxiety disorder to be diagnosed, the person has to report considerable distress over having the anxiety symptoms, or the symptoms have to cause significant interference in the individual's life. In fact, in severe cases, people with anxiety disorders may be unable to work, develop relationships, or even leave their homes. Anxiety disorders often pose an enormous financial burden on society. For example, they often lead to lower work productivity and considerable increases in health care utilization.

Types of Anxiety Disorders

The fourth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*) describes 11 different anxiety disorders. Each of these is listed in Table 1, along with their most important defining features. Although other psychological problems may be associated with extreme fear or anxiety (e.g., eating disorders are associated with a fear of gaining weight), only the conditions listed in Table 1 are officially classified as anxiety disorders in the *DSM-IV.*

Demographic Features of the Anxiety Disorders

Anxiety disorders can occur across a wide range of cultures, ages, sexes, and income levels. In most cases, anxiety disorders are more common in women than in men. The more frequent occurrence in women is most pronounced for Panic Disorder with Agoraphobia and certain specific phobias (particularly animals and storms). For other anxiety disorders, such as Social Anxiety Disorder, blood and needle phobias, and Obsessive-Compulsive Disorder (OCD), the differences between men and women are smaller. The typical onset of anxiety disorders varies, with some tending to begin in early childhood (e.g., animal phobias), others beginning, on average, during the teen years (e.g., Social Anxiety Disorder, OCD), and others tending to begin in early adulthood (e.g., Panic Disorder).

Causes of Anxiety Disorders

Although there are still many unanswered questions about how anxiety disorders begin, a number of contributing factors have been identified. From a biological perspective, there is mounting evidence supporting the role of genetics. In addition, certain neurotransmitters in the brain appear to play a role. For example, OCD appears to be associated with abnormal levels of serotonin, whereas Panic Disorder appears to be associated with abnormalities in the norepinephrine system, as well as others. Differences have also been shown in patterns of blood flow in the brains of individuals with and without anxiety disorders. Interestingly, these patterns may normalize following treatment, either with medication or with psychological treatment.

From a psychological perspective, life experiences appear to play a role in the onset and exacerbation of anxiety disorders. For example, life stress can contribute to the development of Panic Disorder and other anxiety disorders. In addition, traumatic events in particular situations may trigger the onset of Post-Traumatic Stress Disorder (PTSD), a specific phobia, or another anxiety-related problem.

In addition to the role of life events, there is significant

Table 1. Key Features of the Anxiety Disorders

Anxiety Disorder	Key Features
Panic Disorder With or Without Agoraphobia	• The presence of unexpected or uncued *panic attacks* (a panic attack is a rush of fear or discomfort that peaks quickly and is accompanied by four or more associated symptoms, such as racing heart, dizziness, breathlessness, and others). • The presence of anxiety over the panic attacks, worry about the possible consequences of attacks (e.g., dying, losing control, "going crazy"), or a change in behavior related to the attacks. • *Agoraphobia* often occurs with Panic Disorder. This refers to anxiety about, or avoidance of, situations in which escape might be difficult or help unavailable in the event of a panic attack or paniclike symptoms. Feared situations may include crowded places, travel, driving, enclosed places, and others.
Agoraphobia Without History of Panic Disorder	• The presence of Agoraphobia, without ever having met the full diagnostic criteria for Panic Disorder.
Specific Phobia	• An excessive or unrealistic fear of a specific object or situation, such as an animal, heights, blood, needles, elevators, or flying.
Social Anxiety Disorder (Social Phobia)	• An excessive or unrealistic fear of one or more social or performance situations, such as public speaking, conversations, or meeting new people, The fear is of being embarrassed, humiliated, or judged by others.
Obsessive-Compulsive Disorder (OCD)	• The presence of *obsessions* (i.e., thoughts, images, or impulses that are perceived as intrusive and distressing), such as fears of being contaminated, doubts about one's actions, or irrational fears of hurting others). • The presence of *compulsions* (i.e., repetitive behaviors, such as checking, washing, or counting, that are used to reduce anxiety or to prevent something bad from happening).
Post-Traumatic Stress Disorder (PTSD)	• The experience of a trauma in which an individual has been confronted with a threat to his or her physical well-being or to the physical well-being of another individual (e.g., experiencing a rape, assault, or accident; witnessing an act of violence). • 1 month or more in which the individual experiences recurrent recollections of the trauma, avoidance of situations that remind him or her of the trauma, emotional numbing, symptoms of arousal, and hypervigilance.
Acute Stress Disorder	• Similar to PTSD, except with a duration of between 2 days and 4 weeks.
Generalized Anxiety Disorder (GAD)	• Frequent worry about a number of different areas (e.g., work, family, health) with difficulty controlling the worry and a number of associated symptoms (e.g., muscle tension, sleep problems, poor concentration).
Anxiety Disorder Due to a General Medical Condition	• Significant problems with anxiety that are directly caused by a medical condition (e.g., panic attack symptoms triggered by hyperthyroidism).
Substance-Induced Anxiety Disorder	• Significant problems with anxiety that are directly caused by a substance (e.g., panic attack symptoms triggered by cocaine use, caffeine, or alcohol withdrawal).
Anxiety Disorder Not Otherwise Specified	• Significant problems with anxiety that do not meet the official criteria for another anxiety disorder or for some other psychological disorder.

evidence that anxious biases in a person's beliefs, assumptions, and predictions can contribute to anxiety symptoms. For example, individuals with Social Anxiety Disorder tend to be overly concerned that others will judge them in a negative way. Likewise, individuals with Panic Disorder tend to misinterpret normal physical sensations, such as dizziness or breathlessness, as being dangerous.

Treatment of Anxiety Disorders

Anxiety disorders are among the most treatable of psychological problems. Most individuals who receive appropriate treatment experience a significant reduction in symptoms. For Substance-Induced Anxiety Disorders and Anxiety Disorders Due to a General Medical Condition, the focus is generally on reducing the substance use or on treating the medical condition that is causing the problem. However, for the other anxiety disorders, evidence-based treatments include medications, cognitive-behavioral therapy (CBT), or a combination of these approaches.

The selective serotonin reuptake inhibitors (SSRIs), such as paroxetine, fluoxetine, and sertraline, have been shown to be useful for treating most of the anxiety disorders. Other antidepressants (e.g., venlavaxine, imipramine)

are also useful for particular anxiety disorders. Anxiolytic medications (especially the benzodiazepines, such as alprazolam and diazepam) are also effective for reducing anxiety, although they are usually prescribed with caution due to the potential for abuse and the difficulty that some people have discontinuing these drugs. All of the anxiety disorders, except perhaps specific phobias, have been shown to improve following treatment with medications.

CBT includes a number of components. First, patients are encouraged to expose themselves to the situations they fear until their fear subsides. For example, individuals with Social Anxiety Disorder may practice meeting new people, engaging in conversations, or purposely making minor mistakes in social situations. Individuals with Panic Disorder are encouraged to expose themselves to the physical feelings they fear (e.g., running in place until their fear of a racing heart decreases), in addition to the feared agoraphobic situations. In the case of OCD, the exposure is combined with prevention of the compulsive rituals (e.g., touching "contaminated" objects without washing one's hands).

Second, cognitive therapy is often used to help individuals to replace their anxious thoughts with more balanced, realistic perspectives. For example, an individual with Generalized Anxiety Disorder (GAD) who worries whenever his or her spouse is late would be encouraged to consider all of the possible factors that may contribute to the lateness, rather than assuming the worst.

Third, treatment may include teaching the individual other relevant skills. For example, people with GAD often benefit from relaxation or meditation-based treatments. Individuals with Social Anxiety Disorder may benefit from learning to communicate more effectively.

Finally, treatment often includes a combination of medication and CBT. Generally, CBT, medications, and combined treatments are equally effective on average, although some individuals respond better to one approach than another. In the long term, after treatment has been discontinued, symptoms are more likely to return following treatment with medications than they are following treatment with CBT.

APPIC (ASSOCIATION OF PSYCHOLOGY POSTDOCTORAL AND INTERNSHIP CENTERS)

Founded and incorporated in 1968, the Association of Psychology Internship Centers (APIC) was originally constituted as an informal group of psychologists involved in internship training. These trainers banded together for the purpose of sharing information about mutual problems. Over time, the organization expanded to include postdoctoral residency training directors as well as internship training directors, and in 1992 it was renamed the Association of Psychology Postdoctoral and Internship Centers (APPIC).

According to the current mission statement, the APPIC (1) facilitates the achievement and maintenance of high-quality training in professional psychology; (2) fosters the exchange of information among institutions and agencies offering doctoral internships or postdoctoral training in professional psychology; (3) develops standards for such training programs; (4) provides a forum for exchanging views; establishing policies, procedures, and contingencies on training matters and selection of interns; and resolving other problems and issues for which common agreement is either essential or desirable; (5) offers assistance in matching students with training programs; and (6) represents the views of training agencies to groups and organizations whose functions and objectives relate to those of APPIC and develops and maintains relationships with colleagues in those groups and organizations.

The APPIC has a central office in Washington, D.C., which is headed by a full-time executive director. The APPIC board of directors includes seven psychologist members elected by APPIC-member internship and postdoctoral programs and one public member chosen by the other board members. The APPIC also has a number of standing committees whose members are APPIC-member training directors.

The APPIC is a membership and not an accrediting organization. To be accepted for APPIC membership, internship and postdoctoral residency programs must meet specific membership criteria. Membership is automatic for programs accredited by the American Psychological Association (APA) or the Canadian Psychological Association (CPA). The APPIC sponsors a mentoring program to assist new and developing programs in meeting the criteria for APPIC membership. In addition, doctoral-level professional psychology academic programs may choose to become APPIC subscribers, a status that provides specific services to the program and its students.

The APPIC offers a multitude of services. The first APPIC directory was developed for the 1972–1973 training year. At that time, there were 90 internship programs listed and no postdoctoral programs. In the 2002–2003 APPIC directory, a total of 666 APPIC-member programs (588 internships and 78 postdoctoral residency programs) were listed. In addition to the printed APPIC directory, an online and more comprehensive version of the directory was launched in the summer of 2000. The online directory may be updated at any time by training directors, and users may search for programs using a variety of criteria.

Another major service is the facilitation of the internship matching process. For the 1972–1973 through 1998–1999 training years, the APPIC conducted a standardized internship selection process, which utilized a uniform noti-

fication date, to structure a previously unregulated process (Stedman, 1989). In 1999, the APPIC instituted a computer-based internship matching program (called the APPIC Match) to place applicants into available positions (Keilin, 1998). Furthermore, beginning in 1986, the APPIC has operated a postselection clearinghouse to assist both unplaced students and programs with unfilled positions. The matching process further improved in 1996, when the APPIC developed a uniform application for internship, the APPIC Application for Psychology Internships (AAPI).

The provision of information is another key service offered by APPIC, and this occurs in multiple ways. The first APPIC newsletter was published in 1980, and it has served as a major communication forum regarding internship and postdoctoral training issues for member and subscriber programs. The APPIC web site (www.appic.org), along with a variety of e-mail news and discussion lists for trainers and students, also aids in the dissemination of information to member and subscriber programs, intern applicants, interns, and postdoctoral residents. The web site currently has sections covering upcoming APPIC events, the directory, APPIC Match, the clearinghouse, training resources for students and trainers, e-mail lists, and problem resolution. Some of the e-mail lists offer the opportunity for discussion of questions related to the internship and postdoctoral residency application process, jobs, and handling of complex training issues, whereas other lists provide information regarding such diverse topics as the APPIC Match, new funding opportunities, and legislative advocacy efforts. More in-depth sharing of information also occurs at biannual membership conferences and biannual continuing education programs.

One service that the APPIC has provided for many years is the handling of formal complaints from APPIC members, subscribers, or students regarding violations of APPIC policies and procedures. The APPIC Standards and Review Committee (ASARC) investigates these complaints and makes recommendations to the APPIC board regarding the appropriate course of action. More recently, an informal problem resolution mechanism has been implemented. This mechanism is available to all relevant constituency groups and offers members, subscribers, and students an opportunity to seek consultation, guidance, and assistance in resolving conflicts and problems related to APPIC policies and procedures and other internship and postdoctoral residency training issues.

The publication of research data relevant to internship and postdoctoral training has been another service offered by the APPIC research committee. Research findings have been made available on such topics as the supply and demand imbalance or balance (Keilin, Thorn, Rodolfa, Constantine, & Kaslow, 2000), the internship matching process (Keilin, 1998, 2000), and the value of formalized postdoctoral training (Logsdon-Conradsen et al., 2001).

There are myriad ways in which the APPIC has been actively involved in the larger national and multinational psychology education, training, and credentialing communities. The APPIC has ongoing liaison relationships with doctoral, internship, and postdoctoral training councils, as well as credentialing organizations. The APPIC participates actively in various interorganizational groups, including the Council of Chairs of Training Councils, Psychology Executive Roundtable, Council of Credentialing Organizations in Professional Psychology, Trilateral Forum on Professional Issues in Psychology, and Commission on Education and Training Leading to Licensure. The APPIC also has two seats on the Committee on Accreditation of the American Psychological Association (APA).

The APPIC has taken a leadership role in national and multinational psychology conferences. In 1992, the APPIC hosted the National Conference on Postdoctoral Training in Professional Psychology in Ann Arbor (Belar et al., 1993). This conference led to the formation of the Interorganizational Council (IOC), of which the APPIC was a member. The IOC utilized the Ann Arbor document as the basis for formulating recommendations for the accreditation of postdoctoral training programs. As a result of the work of the IOC, since 1996 the Committee on Accreditation of the APA has been accrediting postdoctoral residencies. In response to the supply and demand crisis in psychology, which was related in part to the imbalance in the number of intern applicants and internship positions (Dixon & Thorn, 2000; Keilin, 2000; Keilin et al., 2000; Oehlert & Lopez, 1998; Thorn & Dixon, 1999), in 1996 the APPIC and APA cosponsored the National Working Conference on Supply and Demand: Training and Employment Opportunities in Professional Psychology (Pederson et al., 1997). This conference drew attention to the crisis and led to the development and implementation of multiple strategies designed to reduce this imbalance. Current data suggest that, at least with regard to internship positions, this crisis has improved significantly. In November 2002, APPIC took the lead, hosting, with multiple other sponsoring groups, Competencies 2002: Future Directions in Education and Credentialing in Professional Psychology in Scottsdale.

APPLIED RESEARCH

Definition and Background

Applied research uses the scientific method to solve problems and resolve issues of direct relevance to a given societal need or question. Because it is focused on problem solving within society, it is distinct from basic research, which focuses on pursuit of scientific knowledge for the sole purpose of extending scientific understanding and the knowledge base.

Applied psychologists are Ph.D. graduates of universities where they received extensive training in the scientific method. Within this experimental method, the scientist develops an hypothesis based on existing knowledge and observations. The researcher then formulates an experiment to test the hypothesis, conducting systematic empirical observation and data gathering under carefully controlled conditions. Data are analyzed using appropriate, established statistical methods, and the outcome of the analysis determines whether the hypothesis is supported or rejected.

The distinction between applied and basic research forms a continuum rather than a dichotomy. A neuroscientist, for example, may seek to determine whether neuronal lesions in the hippocampus accelerate neuronal sprouting—a basic psychology question to further knowledge about the way the brain functions. As the scientist applies drug treatments to these lesions, she or he may discover a drug that effectively accelerates the sprouting process. This discovery, in turn, may prove to have long-range applicability for patients who have suffered some form of spinal injury and resulting paralysis. Although the beginning point was not to address a societal problem, the findings may prove to have direct societal applicability. On this basic/applied continuum, many outcomes of basic research have proved relevant in addressing given societal problems. The distinction lies in the starting point—whether the societal problem was directly addressed within the research or whether the research sought solely to extend the existing scientific knowledge base.

History

As early as 1908, Hugo Munsterberg stated, "The time for . . . Applied Psychology is surely near, and work has been started from most various sides. Those fields of practical life which come first in question may be said to be education, medicine, art, economics, and law" (Marciano, 1999). Hailed as "the first all-around applied psychologist in America," Munsterberg shaped the field, brought definition to it, and outlined its potential uses in business and industry (Spillman & Spillman, 1993). Equally significant was the pioneering influence of Walter Dill Scott. In the same year that Munsterberg predicted applied psychology's era, Scott was bringing that era still closer to fruition with his book *The Psychology of Advertising.* Seven years later he again pioneered as the first psychologist to receive an appointment as professor of applied psychology at an American university (Carnegie Institute of Technology).

The early branches of applied research reflected closely the industrial orientation of their pioneers. Three of the basic research disciplines gave early birth to applied research offspring. Psychological testing produced personnel selection and classification; experimental psychology parented human factors engineering; and personality/social psychology provided the background setting for work in employee relations. The early history of applied research is, in effect, the history of industrial psychology as well.

World War II Landmark

Prior to the 1940s, the vast majority of psychologists were associated with universities and were conducting basic research. World War II brought with it an unprecedented range of problems that required rapid scientific attention. Not all aviator recruits were created equal in their ability to fly planes, and selection methods were needed to determine those best suited for piloting. Elsewhere in the war scenario, a highly sophisticated Nazi propaganda network challenged our effective counterresponse. American citi-

zens' attitudes toward given food and product consumption needed to be changed in support of the war effort. And returning war veterans brought with them psychological and emotional problems in massive numbers unprecedented within the U.S. mental health community. The pressure of such severe mental and emotional distress in such mammoth proportions confronted a formerly basic research discipline with a real-world clinical problem of incredible magnitude. In these areas and others, applied research came to the front line and needed to respond scientifically, effectively, and rapidly.

Range of Applied Research Settings

The range of applied research settings spans the broad range of society itself. Problems are scientifically addressed in settings ranging from hospitals, clinics, and other human service facilities to the areas of business and industry, courts and correctional institutions, law enforcement and community policing, government and military services, consulting and research organizations, clinical and counseling practice, and community planning.

The problems and questions are as wide-ranging as the settings themselves. Hospitals and clinics may need help in addressing problems that relate to preparing patients and their families for major surgery or working with those who have experienced a specific type of trauma. Business and industry may need assistance in personnel selection for given positions "on the line" or in upper-level management. A given industry may need to determine how to most effectively design a work space within a factory or the controls within an airplane cockpit to minimize fatigue and maximize performance efficiency. Community planners may need to know what elements and architectural designs to build into their communities in order to create living spaces and communities conducive to positive social interaction and emotional health. Schools may need to effectively test student strengths and counsel these students on compatible career matches. All of these and related questions require the knowledge, expertise, and training of applied psychology and applied research.

Basic/Applied Tension

The formally stated goal of the American Psychological Association (APA) gives testimony to the tension and growth that applied research has brought to the discipline. The APA's goal is "to advance psychology as a science, a profession, and as a means of promoting human welfare."

No members of the profession felt this implication more prominently than did clinical psychologists. Unable to meet their applied-research and psychotherapy-orientation needs within the APA, they formed state and national splinter groups (e.g., the American Association of Applied Psychology, Psychologists Interested in the Advancement of Psychotherapy) where their applied research interests and activities could be effectively and meaningfully shared. The fact that splinter groups and their members now live under the APA roof is prominent evidence of the professional growth that has occurred within the APA. It is also a tribute to the efforts of pioneers such as Carl Rogers who devoted extensive time and personal energy to the task of unifying. The threefold goal—science, profession, human welfare—has now attained a visible balance within the professional activity and commitments of the APA.

Concurrently, basic researchers within colleges, universities, and research centers created a mirror image of the earlier splintering. Convinced that the APA had now become a predominantly applied professional organization, they founded the American Psychological Society (APS). The organization's stated purpose, resonant of the APA's, sets the goal "To promote, protect, and advance the interests of scientifically oriented psychology in research, application, and the improvement of human welfare." Many psychologists hold membership in both organizations, and only the future can determine whether the APA and APS will continue as separate identities.

Rapid Growth and Societal Need

The growth and complexity of societal questions and needs have spawned a corresponding growth in applied research. Whereas only a few applied research divisions existed in the American Psychological Association 50 years ago, several applied research divisions exist today. Among them one finds such divisions as The Society for the Psychological Study of Social Issues, Consulting Psychology, The Society for Industrial and Organizational Psychology, and Education/School/Counseling Psychology. Other divisions relate to such areas as public service, military psychology, adult development and aging, rehabilitation, consumer psychology, psychopharmacology and substance abuse, mental retardation and developmental disabilities, and population and environment. The divisions are as vast and wide-ranging as societal needs themselves.

As one views the vast range of areas and divisions it becomes readily apparent that applied research will continue its rapid growth. Within this growth there is the ever-present danger that psychologists may fragment into their respective avenues of applied issues and problems. At the same time, it is well to remember that all are united in their scientific background training and their commitment to the scientific method, empirical observation, and systematic data gathering and analysis.

APPROACH-AVOIDANCE CONFLICT

Approach-avoidance conflict occurs when approach and avoidance tendencies of similar strength are opposed to each other. More generally, "conflict occurs when two or more incompatible reaction tendencies are instigated simultaneously" (Kimble, 1961). Conflict can involve approach-approach, avoidance-avoidance, approach-avoidance or multiple combinations of these. "Approach-avoidance conflict is by far the most important and the most common form of conflict in animal behavior" (McFarland, 1987). Both approach and avoidance can be produced by stimuli that generally do so in a particular species without previous experience. The kind of behavior produced by these "innate" stimuli helps us understand function. Other stimuli produce approach and avoidance only after learning. Their effects can help us understand control mechanisms. Approach-avoidance conflict is currently important for identifying antianxiety drugs (File, 1992) and for analyzing the brain areas involved in human anxiety disorders.

By looking at natural conflict in the wild (ethology), observers have discovered some complex patterns of behavior. Suppose food is close to danger. Animals will approach while they are far from the food (and danger) but will move away again when too close to the danger (and food). They will usually finish up in an ambivalent posture at some intermediate distance (see, e.g., McFarland, 1987). The problem is how to get your lunch without becoming lunch for someone else. The high survival value of solving this problem has led to ritualization of behavior in many conflicts. "Conflict behaviour is [also] often replaced by other seemingly irrelevant, behaviour . . . termed displacement activity" (McFarland, 1987). So conflict can produce a mixture of approach and avoidance behavior. In a simple robot this mixture would result in unending oscillation at an intermediate distance, but it often produces a variety of complicated and sometimes apparently bizarre behaviors. These behaviors can resolve the conflict by providing new information or by allowing the animal to ignore an insoluble problem and get on with other business.

Analysis of approach-avoidance conflict in the laboratory provides some explanation of the ethological observations. In 1944, Miller (Miller, 1944; Kimble, 1961; Gray, 1987) proposed a model, the details of which have since been essentially confirmed. Both the tendency to approach a desired object and the tendency to avoid a feared object increase as the object gets closer to the animal. This has been measured in terms of the strength with which the animal will pull toward or away from the object (Gray, 1987). The avoidance gradient is steeper than the approach gradient. Thus, at large distances the animal approaches, whereas at short distances it avoids, and at equilibrium conflict behavior is observed (see Gray, 1987, for cases in which the avoidance gradient may be reduced).

Recently, ethoexperimental analysis (Blanchard & Blanchard, 1989) has extended this picture to include temporal as well as spatial distance. (Ethoexperimental analysis involves the use of ethological measures and experimental manipulations within an ecologically consistent laboratory setting.) When a cat is present, rats avoid an arena containing food. When there is no sign of a cat, rats enter the arena and eat the food. When a cat has recently been present or when the smell of a cat is present, the rats engage in an approach-avoidance oscillation accompanied by risk analysis behavior. Here, extensive assessment of the environment and the use of a stretch-attend posture may be seen not as ritualization or displacement activity but as behavior that will actively resolve the conflict (in favor of approach or avoidance) by gathering new information.

Blanchard and Blanchard (1989) ascribe pure avoidance to fear and distinguish this from risk analysis in the presence of threat, which they ascribe to anxiety. The implied relation between these behaviors and equivalent human clinical dysfunction is supported by the fact that the former are sensitive to antipanic agents and the latter to antianxiety agents (Blanchard, Griebel, Henrie, & Blanchard, 1997). Much conventional experimental analysis suggests that avoidance within an approach-avoidance conflict (resulting from either fear or frustration) is sensitive to antianxiety drug action, whereas pure avoidance (resulting from fear or frustration) is not (Gray, 1977). As with the ethological analysis, this suggests that approach-avoidance conflict involves more than a simple balance between approach and avoidance. It involves special mechanisms to produce ritualized behavior and displacement activity. The drug data show that conflict increases avoidance tendencies. In the wild, this would produce a more "safety-first" attitude than if approach and avoidance were simply allowed to sum arithmetically.

A shift toward risk taking in approach-avoidance conflict with little change in pure approach or pure avoidance

is characteristic not only of antianxiety drug action but also of septal and hippocampal lesions. Thus, antianxiety drugs appear to change approach-avoidance conflict by impairing hippocampal function (Gray, 1982). The septo-hippocampal system appears to receive information about approach and avoidance tendencies, to detect conflicts, and (particularly with approach-avoidance conflict) to increase avoidance tendencies (Gray & McNaughton, 2000). Given the previous distinction made by Blanchard and Blanchard (1989) between fear and anxiety, this theory holds that Generalized Anxiety Disorder (but not simple phobia or panic) involves hyperactivity of the septo-hippocampal system (McNaughton, 1997). This hyperactivity can be viewed as increasing the level of fear (or of anticipation of loss of reward). It thus moves the point of intersection of the approach and avoidance gradients further from sources of threat.

Approach-avoidance conflict, then, has been under detailed investigation for many decades; a clear picture is now emerging of its structure, function, and psychological properties. Dysfunction of the mechanisms controlling approach-avoidance conflict appears fundamental to Anxiety Disorders. Detailed neural mechanisms, and sites of action of therapeutic drugs on those neural mechanisms, are now being discovered as substrates of the psychological processes involved (Crestani et al., 1999). Of particular cause for optimism, ethology, behavior analysis, cognitive psychology, psychopharmacology, and behavioral neuroscience appear to be combining to produce a single, coherent, integrated, story in this area.

APTITUDE TESTING, IMPORTANCE OF

Aptitude testing involves estimating an individual's potential to perform a criterion of interest on the basis of measures of that individual's knowledge, skills, abilities, and other attributes. Such testing is important for selection efforts, such as determining who has the greatest likelihood of excelling in a school, career, or training program. Aptitude testing also is central to personnel classification—that is, matching individuals to jobs or job tasks on the basis of aptitudes. Since many aptitudes exhibit developmental change, aptitude testing also is important for validating theories of the nature and course of such change (English, 1998).

Assessment can be *concurrent,* in which case the aptitude test, or *predictor,* and the outside criterion against which the predictor is being validated occur at the same point in time. The assessment can be *predictive.* In these efforts, the predictor occurs in the present, and the criterion will occur in the future. Alternatively, the assessment can be *postdictive,* as when the predictor occurs in the present, and the criterion has occurred in the past.

The results of aptitude assessment can fruitfully be linked to interventions in educational, occupational, and clinical settings (Sternberg, Torff, & Grigorenko, 1998). In addition to measuring learning, tests can be *agents* of learning. Such *learning tests* are designed to foster learning during assessment (Dempster, 1997).

Issues In Aptitude Test Design and Development

Researchers are interested in elucidating (1) relationships between aptitudes and the criterion measures that the aptitudes predict, (2) types of aptitudes being measured and interrelationships between the aptitudes, (3) the manner in which the aptitudes are measured, and (4) the psychomet-

ric properties of tests in given testing sessions. Psychometric issues include standardizability, reliability, validity, and adverse impact.

Test administration issues include the time available for testing, resources and technology needed for administration and scoring of aptitude tests, and adaptability of tests and testing equipment for different test sites. *Test utility* issues include ease of administration, costs associated with training test administrators, maintaining test sites and equipment, and preparing test materials. *Implementation* of testing programs that have broad applicability in a timely manner remains an important challenge. Furthermore, tests should be designed so that the resulting information, when used in selection and classification efforts, minimizes attrition.

Conceptions of Aptitude

Theoretical notions regarding the origins of aptitude guide approaches to aptitude testing and directly address the above issues (Dillon, 1997; Flanagan, McGrew, & Ortiz, 2000). Performance on aptitude tests may result from a range of biological, cognitive, and social factors including (1) activation of competence, (2) trainability, (3) changes in learning and development resulting from mediated learning experiences, (4) guided experience, and (5) direct experience (Gottfredson, 1997).

Aptitude Testing Framework

Testing paradigms can be considered along four dimensions: aptitudes, methods, measures, and timing.

Aptitude Dimensions

The level of specificity of predictors, domains tapped, and the prior-knowledge demands of aptitude tests are all important factors in aptitude testing. Aptitude dimensions range from neurophysiological, electrophysiological, and perceptual processes to information-processing components (Dillon, 1997) and metacomponents (Sternberg, 1998; Sternberg, Torff, & Grigorenko, 1998); knowledge and reasoning aptitudes (Dillon & Vineyard, 1999); school subject aptitudes (Jacobs, 1998; Skehan, 1998; Sparks & Ganschow, 1996); sociocultural attributes (Lopez, 1997); personality, temperament, attitude, and motivational attributes; and interpersonal attributes such as social problem-solving aptitudes, including environmental adaptation aptitudes.

Information-processing theory and methodologies have enabled researchers to decompose reasoning and other IQ test-type tasks into their distinct information-processing components, such as encoding, rule inference, rule application, and confirmation. Researchers have studied the functioning of these component processes during complex thinking and problem solving (e.g., Dillon, 1997; Sternberg, 2000), and they have developed methods and measures to test attributes that occur in everyday life, such as tacitly acquired knowledge (e.g., John & Mashna, 1997). Considerable attention has been paid to issues in special education testing (Carver & Clark, 1998; Forness, Keogh, & MacMillan, 1998; Greenspan & McGrew, 1996) and aptitude testing in gifted education programs (Sternberg, 1998). In addition to enhancing understanding of one's possession of various abilities, research in cognitive flexibility has helped scientists to understand the manner in which individuals select and deploy tactics as the demands of a task or situation warrant (Dillon & Vineyard, 1999; Fox, 1997).

Methods of Test Administration and Measures Taken From Tests

Methods of test administration and data collection include computerized adaptive testing, dynamic testing (Dillon, 1997; Sternberg & Grigorenko, 2002), paper-and-pencil testing, observational data collection, document analysis, portfolio assessment, and job sample measures. Conceptions of aptitude differ in the nature of the databases on which the different models rest. Some researchers use complex and extensive statistical methods to uncover mental structures and processes. Other researchers base their conceptions of aptitude on interpretations of psychological observations and experimental findings. Still other researchers employ psychophysiological, neurophysiological, electrophysiological, or information-processing paradigms, sometimes coupled with experimental manipulations. Finally, some researchers use *curriculum-based assessment* (CBA) or *performance assessment* (PA) paradigms, which boast connections between assessment, curriculum development, and instruction (Cantor, 1997; Elliot, Braden, & White, 2001; Elliott, Kratochwill, & McKevitt, 2001).

Timing

Aptitude tests can be given to determine who has the highest probability of succeeding in a particular education or training program. Aptitude tests also can be given prior to initial job selection. Subsequent to job selection, testing is used for the purpose of classification to particular jobs. Testing also is undertaken for job enhancement, such as for retention, promotion, or selection to advanced training programs.

Aptitude models are validated against a variety of school and occupational arenas. Common criterion measures include performance in (1) high school and college, (2) military training, (3) medical school preparation courses and medical school, and (4) complex workplace activities.

Testing in the Twenty-First Century

According to Kyllonen (1996), researchers should develop testing systems that are broad-based, precise, quick, and implemented in a short time frame. In addition, important

technology, including computer delivery; item-generation technology; multidimensional adaptive technology; comprehensive cognitive aptitudes and abilities measurement; time-parameterized testing; and latent factor-centered design should be utilized.

ARCHETYPES

Carl Jung introduced the term *archetype* into psychological theory, and he is primarily responsible for the development of the concept to which it refers. Jung recognized two basic layers in the unconscious—the personal unconscious, whose contents are derived from present lifetime experience, and the collective unconscious, whose contents are inherited and essentially universal within the species. The collective unconscious consists of archetypes. Jung described these as primordial images that have existed from the remotest times, but images that lack clear content. Their specific content as realized images is supplied by the material of conscious experience. Thus, the archetype as such is an empty form that must be inferred, or derived by abstraction, from a class of experienced images or symbols.

Jung (1969) noted that the term was first used by Philo Judaeus and later appeared in the writings of Irenaeus and Dionysius the Areopagite. In such ancient uses, it had a meaning close to that of Plato's *ideas*. A similar concept recurs over the centuries in idealistic philosophy and was emphasized by Romantic philosophers of the nineteenth century.

Jung acknowledged an intellectual lineage that can be traced to Plato, but he contended that his use of the term *archetype* is more empirical and less metaphysical than the use of the same or corresponding terms by idealistic philosophers. He arrived at the concept initially through a study of psychotic patients and augmented his understanding through a more comprehensive study of symbol systems. To the extent that he used experience as a springboard for theory, Jung can be regarded as more Aristotelian than Platonic. Yet, to the extent that Jung's theory of ar-

chetypes is valid, it leads to the paradoxical conclusion that only a limited empiricism is possible. For Jung, the archetypes are the most fundamental ingredients of the whole psyche. They are the forms that underlie everything we perceive, imagine, and think. Through progressive accumulation and elaboration of specific contents, the archetype becomes manifest in the image and then in the conscious idea, and even the basic concepts of philosophy and science can be regarded as ultimately rooted in archetypal forms. Thus, while Jung's concept of the archetype may be partly empirical, it necessarily rests on its own archetypal base.

Jung noted that this concept is akin to that of the instinct. Each term refers to an inborn predisposition, and in each case it is a predisposition that must be inferred from a certain class of effects. The term *instinct* refers to a predisposition to act in a certain way, whereas *archetype* refers to a predisposition toward a certain kind of "psychic apprehension." One might surmise that in both cases we are dealing with a tendency that has evolved and become universal within a species because it has survival value. Jung, however, did not provide a biological rationale for the archetype, and he considered it rather futile to speculate on its origin. He merely suggested that if the archetype ever "originated," its origin must have coincided with that of the species.

Jung began to develop the archetype concept during his early work at the Burghölzli Hospital, where he observed that some of his relatively uneducated psychotic patients experienced universal religious and mythological symbols. In many instances it was clear that the patient could not have learned of the symbol through formal study, and the appearance of the symbol in the patient's ideation or imagery had to represent a spontaneous eruption of unconscious material not derived from experience during the present lifetime. Jung subsequently explored the archetypal realm through an intensive examination of his own dreams and waking fantasies. He developed a method of "active imagination," by which he was able to secure a spontaneous flow of dreamlike material in a waking state. He studied religious symbolism, mythology, tribal lore, and such occult disciplines as alchemy in quest of evidence of universal motifs. Thus, his conclusions can be said to rest on an extremely broad base of observational data.

The archetypes to which Jung devoted the greatest amount of attention in his writings include the shadow, the anima and animus, the wise old man, the magna mater (or great earth mother), the child, and the self (Jung, 1968). Each of these archetypes collects a great deal of associated content, which varies according to the experience of the individual and colors a large portion of our total experience. The behavioral, intellectual, and perceptual qualities over which we fail to develop much conscious control remain with us as a kind of unexamined dark side and become associated with the shadow. The feminine qualities that a man fails to realize consciously in himself become associated with his anima, while the unrealized masculine qualities of the woman become associated with her animus. Thus, each archetype becomes the core of a system of content that varies a bit from one individual to another.

The archetypes noted above tend to be experienced in personified form. They may appear as figures in our dreams, and they provide the source of such cultural symbols as gods and goddesses. They also enter extensively into our interpersonal experience, for we frequently project them onto other people. Each of these archetypes can be expressed in a great variety of personifications. A given anima image, for example, may be positive or negative and may emphasize any of a number of possible qualities—sexuality, beauty, wisdom, spirituality, moral virtue, destructiveness, and so forth. There are other archetypes, which Jung (1969) called archetypes of transformation, that do not appear in a personal form. They are expressed in many of the situations, places, implements, and events of our dreams, and they govern corresponding motifs in folklore. Jung believed he had identified the most important archetypes. Yet, if his basic assumptions are valid, it may be assumed that the total number of archetypes is indefinitely large and that an exhaustive inventory is not feasible.

ASIAN PSYCHOLOGIES

Within the new global context of our lives, Western psychology will need to be repositioned as one of many psychologies worldwide, rather than as the only or dominant psychology.
—Marsella (1998, p. 1286)

Overview

Until recently, Western psychologists assumed that their own psychologies were the only ones worthy of serious consideration, but this unfortunate attitude is changing rapidly.

We will limit discussion here to four Asian psychologies—the Yogic and Buddhist psychologies of India and the Taoist and neo-Confucian systems of China. These also display significant commonalities and have therefore been referred to as aspects of the "perennial wisdom," "perennial psychology," or "consciousness disciplines."

Researchers increasingly describe development as pro-

ceeding through three major stages: preconventional, conventional, and postconventional (or prepersonal, personal, and transpersonal). Psychotherapies address three correlative levels of health: pathology reduction, existential issues, and transpersonal concerns. Western psychologies have developed sophisticated prepersonal and personal maps and therapies. By contrast, Asian psychologies focus almost exclusively on existential and transpersonal concerns and offer little on early development or severe psychopathology.

Personality

Asian psychologies both derive from and lead to ideas about human nature, health, pathology, and potential that in certain ways differ significantly from traditional Western views. We can summarize the Asian claims under the headings of consciousness, identity, motivation, psychopathology, and psychological health.

Consciousness

In *The Varieties of Religious Experience* William James (1958, p. 298) concluded:

> Our normal waking consciousness . . . is but one special type of consciousness, whilst all about it, parted from it by the filmiest of screens, there lie potential forms of consciousness entirely different. . . . No account of the universe in its totality can be final which leaves these other forms of consciousness quite disregarded.

Asian psychologies agree completely. They recognize multiple states and that some states of consciousness may be associated with specific functions and abilities not available in our usual state. Perceptual sensitivity, attention, and the sense of identity, as well as affective, cognitive, and perceptual processes may all vary with the state of consciousness in precise and predictable ways.

"Higher" states possess the effective functions of the usual states, plus heightened perceptions, insights, or affects outside the realm of day-to-day experience. If higher states exist, then our usual state must be suboptimal. This is exactly the claim of Asian psychologies. They argue that our usual state of consciousness is underdeveloped, constricted, and dreamlike, to a remarkable but usually unrecognized degree. Thus the normal person is seen as "asleep" or "dreaming." When the dream is especially painful or disruptive, it becomes a nightmare and is recognized as psychopathology. However, since the vast majority of the population "dreams," the true state of affairs goes unrecognized. When individuals permanently disidentify or "awaken" from "dreams," they are able to recognize the true nature of both their former state and that of the population. This awakening, known variously as *wu, moksha* liberation, or enlightenment, is a central aim of Asian psychologies.

In part, this is an extension of traditional Western psychology, which has long recognized a broad range of perceptual distortions, unrecognized by naive subjects. But Asian psychologies assert that these distortions are more pervasive and harmful than usually recognized but that these distortions can be recognized and reduced by specific mental training and that doing so fosters psychological development to transconventional, transpersonal levels.

Identity

Western psychologists usually assume that our natural and optimal identity is "egoic," implying a sense of self inextricably linked to the body and separate from other people and things. Asian psychologies suggest that our egoic identity is unnecessarily constricted, resulting in egocentricity, selfishness, and suffering. They also suggest that a more mature, expansive identity is possible and that this claim is directly testable by anyone willing to cultivate perceptual sensitivity via meditative-Yogic practices.

Asian psychologies also suggest that existential and psychoanalytic claims about the impossibility of resolving psychodynamic conflicts and existential givens such as finitude, meaning, and suffering are indeed correct at the egoic level. Existentialists might be said to have rediscovered part of the Buddha's first Noble Truth: that unsatisfactoriness is part of life and (for the untrained mind) is accompanied by angst. However, the Buddha went further, and in the remaining three Noble Truths pointed to a crucial cause of suffering (addiction or craving) and the means for escaping it.

Motivation

Asian psychologies, especially Yogic psychology, tend to see motives as hierarchically organized in a manner analogous to that suggested by Abraham Maslow (1971) and Ken Wilber (2002). However, Asian psychologies emphasize the importance of "higher motives," such as self-transcendence and selfless service, which are rarely recognized in Western psychology.

One motivational factor that is given great emphasis and viewed as a major determinant of pathology and suffering is attachment (or addiction). From this perspective, psychological suffering is a feedback signal, indicating the existence of attachments and the need to let them go.

Attachment invariably gives rise to its mirror image: aversion. Whereas attachment says "I must have something in order to be happy," aversion says "I must avoid something in order to be happy." Aversion is said to underlie anger and aggression.

Psychopathology

The Asian view of psychopathology centers on three ideas: immaturity, unhealthy mental qualities, and the "three poisons" of greed, hatred, and delusion.

Asian psychologies regard our usual adult state as a form of arrested development and would agree with Abraham Maslow (1968, p. 16) that "it seems more and more clear that what we call 'normal' in psychology is really a psychopathology of the average, so undramatic and so widely spread that we don't even notice it ordinarily." From this perspective, development has proceeded from preconventional to conventional but has then faltered and ground to a premature halt. At this stage the mind operates suboptimally, many potentials and capacities remain unrealized, and various unhealthy mental qualities flourish.

These unhealthy qualities include, for example, attentional difficulties such as distractibility and agitation, cognitive deficits such as mindlessness, disruptive emotions such as anger and jealousy, and problematic motives such as sloth and selfishness. The most fundamental pathological factors are sometimes said to be the three poisons of delusion, attachment and aversion.

Psychological Health

The Asian ideal of health extends beyond pathology reduction to encompass existential and transpersonal concerns. Health is defined primarily in terms of three changes: (1) the reduction of unhealthy qualities, especially the three poisons, (2) cultivation of healthy qualities, and (3) maturation to transpersonal stages of development.

Asian psychologies emphasize that specific healthy mental qualities must be deliberately cultivated to ensure psychological health and maturity, for example, concentration, compassion, and mindfulness. The quality of mindfulness—precise awareness of the nature of the stimuli being observed—might be regarded as a highly developed form of the Freudian "observing ego."

Psychological health also includes maturation to transpersonal stages and capacities. These include, for example, postformal operational cognition and wisdom, postconventional morality, transpersonal emotions such as encompassing love and compassion, and metamotives such as self-transcendence and selfless service.

Asian Disciplines and Therapies

The applied side of Asian psychologies focuses on disciplines and therapies designed to foster psychological and spiritual development and well-being. The best-known disciplines are meditation and yoga. Meditation refers to a family of techniques that train awareness and attention in order to bring mental processes under greater voluntary control. This control is used to reduce destructive mental qualities; to cultivate beneficial qualities such as concentration, compassion, and insight; and to enhance psychological and spiritual growth and well-being. Yogas are more inclusive disciplines that encompass meditation, ethics, lifestyle modification, body postures, breath control, and intellectual study.

In addition to specific meditative and Yogic techniques, Asian systems, like contemplative traditions around the world, emphasize seven central practices and goals.

1. Redirecting motivation and moving up the hierarchy of needs, especially by reducing attachment and aversion
2. Transforming emotions, especially reducing problematic ones such as anger and fear, and cultivating beneficial emotions such as love and compassion
3. Living ethically so as to reduce destructive mental qualities such as greed and attack, and to foster helpful qualities such as empathy and generosity
4. Developing concentration
5. Enhancing awareness
6. Fostering wisdom
7. Increasing generosity and altruism

To give just two examples of Asian techniques and resultant skills—which until recently Western psychologists considered impossible—consider the cultivation of love and lucid dreaming. Several meditations are specifically designed to cultivate the encompassing, unconditional love known as *bhakti* in the East and *agape* in the West. Dream yoga is a 2,000-year-old discipline for developing lucid dreaming: the ability to know one is dreaming while still asleep. Advanced practitioners claim to maintain awareness and continue meditation and mind training throughout the night, a claim now supported by electroencephalographic studies. These capacities hint at the remarkable abilities, developmental possibilities, and powers of mind—some as yet unrecognized by Western psychologists—that Asian psychologies have discovered in their 3,000-year-long exploration of our inner universe. The Swiss psychiatrist Medard Boss (1963, p. 188), one of the first Westerners to examine Asian practices, suggested that compared with the extent of Yogic self-exploration "even the best Western training analysis is not much more than an introductory course." However, even modest amounts of practice can produce significant psychological, physiological, and therapeutic changes, as several hundred experiments and clinical studies have shown.

Because they focus on different aspects of health and development, Asian and Western psychologies may be partly complementary. One of the major challenges for the twenty-first century will be to synthesize Asian and Western systems into an overarching integral psychology that honors and includes both. The writings of Ken Wilber provide the best example to date of this possibility.

ASSERTIVENESS TRAINING

Assertiveness training (AT) was introduced by Andrew Salted, developed by Joseph Wolpe, and popularized by Wolpe and Lazarus. Rarely used alone, AT is used most frequently as one aspect of a broader therapeutic program. The goals of AT include (1) increased awareness of personal rights; (2) differentiating between nonassertiveness, assertiveness, aggressiveness, and passive-aggressiveness; and (3) learning both verbal and nonverbal assertiveness skills. Assertiveness skills involve saying "no"; asking for favors or making requests; expressing positive and negative feelings; and initiating, continuing, and terminating conversations.

Assertiveness training, as generally practiced, requires determining the specific situations where the client characteristically behaves maladaptively, that is, either unassertively, aggressively, or passive-aggressively. While self-report inventories are available for assessing the client's general responses to situations that require assertiveness, most contemporary assertiveness inventories are constructed to be situation specific. Behaviorally, though it is desirable to observe the client in the actual problematic situation, it is routine to role-play the unassertive or passive interaction with the therapist.

If assessment demonstrates that the client is always unassertive, aggressive, or passive-aggressive, then more traditional therapies are recommended. However, if there are specific troublesome situations where the client could perform with increased assertiveness, AT is indicated. Clients are often resistant to AT because of cultural, familial, or religious proscriptions against being assertive. These reservations require careful consideration and discussion, if AT is to proceed efficiently.

There is no universally formulated program called Assertiveness Training. The personal predilections of the therapist determine the course of therapy. However, the following five methods are commonly utilized to generate increased assertiveness in specific situations. First, *response acquisition learning* involves increasing assertiveness through modeling and behavioral instruction. The focus is on the verbal, nonverbal, cognitive, and affective components of assertiveness. Second, *response reproduction* includes performing the new responses using role-playing, behavior rehearsal, or response practice. Third, *response refining* uses shaping and strengthening the new behavior with appropriate feedback and coaching. Fourth, *cognitive restructuring* challenges irrational beliefs that interfere with assertiveness and generates cognitions that promote assertive behavior. Finally, *generalization instruction* involves attempting new behavior in vivo and encourages transfer to new situations. The above procedures are continued until the client demonstrates appropriate assertiveness. Typically, there are five steps in AT: (1) recognize your own feelings (e.g., disappointment), (2) recognize the other person's feelings, (3) reflect the other person's feelings, (4) express your own feelings, and (5) request a behavior or behavioral change from the other person.

Early formulations about the theoretical basis for AT assumed either an anxiety-produced response inhibition or an unassertive response skills deficit. Current research has established the importance of cognitive and information-processing factors in generating assertive behavior. Cognitions that limit assertion include unassertive irrational beliefs, inappropriately stringent self-evaluative standards, and faulty expectations concerning the consequences of behaving assertively.

Recent AT research has focused on reducing anxiety in psychiatric patients, providing stress management training, using AT in school settings to reduce aggressive behavior, enhancing social skills training, developing sex education programs, and increasing self-confidence in college students. Assertiveness training is also being used in Behavioral Health and Behavioral Medicine programs for lowering blood pressure, smoking cessation, and anger control.

ASSISTIVE TECHNOLOGY

Definition

Assistive technology (AT) is anything scientifically or technically manufactured that serves to assist or improve normal function. It can include manufactured items that serve humans, ranging from clothing that enhances functioning in cold weather to airplanes that speed movement from one place to another. The term is not restricted to its use by people with disabilities (PWDs) for technological devices or programs that are useful to them. However, the field of rehabilitation of people with physical or sensory disabilities has co-opted the term to some extent to refer to utilization by PWDs without actually defining the nature or the extent of the disability. Thus the term, as used in rehabilitation, includes all types of devices and programs, regardless of

complexity or technical level, from eyeglasses to mechanical ventilators and from computer-assisted communications to programmed heart monitors, that may improve the physical and psychosocial conditions of a PWD. According to the U.S. Technology Act, reauthorized in 1998, AT is defined as "[a]ny item, piece of equipment or product system, whether acquired commercially off the shelf, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities." While the act refers only to the functional capabilities of AT, the thrust of research by psychologists into AT in rehabilitation has been AT's psychosocial impact.

The interest of psychology in AT is twofold. The first is to study the effects of AT on the life of its consumer, especially the effects on psychosocial aspects such as quality of life (QOL). The second is in outcome research, especially to explore reasons for the adoption of assistive devices and for the high level of their abandonment.

Quality of Life

Enhancement of QOL is an accepted goal of rehabilitation, and its study is becoming very important in the field of rehabilitation psychology. Originally, QOL was an area that had been dominated by economists, sociologists, and some other social scientists. The first public mention of QOL was in a speech by an early spokesperson for President Johnson in which it was stated:

> The task of the Great Society is to ensure our people the environment, the capacities, and the social structures that will give them a meaningful chance to pursue their individual happiness. Thus the Great Society is concerned not with how much, but with how good—not with the quantity of the goods, but with the quality of our lives.

But a close reading of the speech suggests that what was really discussed was *standard of life* rather than its quality, as noted in the emphasis on the interaction between the person and the environment. In fact, the people assigned to assess whether people were getting what was being promised were economists and sociologists, and they defined QOL in terms of the nature of the environment and the assets that people possessed. Thus they would include "domains," such as "number and quality of parks in the district," "the number of robberies in the community," and "the number of television sets in the home." Different people chose to include different domains in their final indices of QOL, and so the index varied with the researcher. Although this seemed to them to be an acceptable way of conceptualizing and measuring QOL, it was rejected by others in different countries who argued that one could have an equally high QOL without the greater abundance of goods and conditions found in the United States. In fact, comparisons of QOL of people in different communities generally failed to indicate significant differences.

Psychologists also argued that one should avoid concentration on being "well-off" and focus on a concern of "well-being." Furthermore, they argued that personal satisfaction with one's standard of life was the key to understanding the meaning of QOL and that one might possess very little but be satisfied or dissatisfied with whatever one had.

If we are to understand the impact of AT on a consumer, we must be aware that there are different impacts, each of which depends on the nature of the consumer and that of the device or program. The best analogy is probably that of the pyramid postulated by Maslow to illustrate the hierarchy of needs. In the bottom levels, he argued, are found the biological needs, and these must be gratified before the next levels become potent. The middle levels are the person-environment interactions in which the individual strives to gain reward from the surrounding world, including both external and internal environments. Finally, at the peak, which Maslow termed *self-actualization,* is the need for inner satisfaction from life as a whole and the search for fulfillment of the needs for satisfaction in life experience.

Similarly, AT impacts on comparable levels. At the lowest level we find that the impact is biological and serves to extend life biologically. This can be termed *quantity of life.* Mechanical ventilation for people with ALS disease is an example of where AT has its strongest impact. At the intermediate level one finds that the impact is mainly on the standard of life. Wheelchairs, for example, impact on consumers so that they can interact more easily with the environment. At the peak of the pyramid, the impact is on the QOL, a term that should be reserved to denote the inner satisfaction derived from the assessment of the whole life process. Consumers find that by utilizing AT they are more satisfied with their lives and have greater self-confidence in their actions. Although AT can impact on all three levels, most AT devices impact on both the standard of life and the QOL levels.

Measurement of Impact on QOL

Change in QOL is an outcome variable that has import on the acceptance or abandonment of an AT device or program. The measurement of impact on QOL therefore becomes an important line of research. Commonly, the person interested in demonstrating effectiveness of an intervention will fashion an index of QOL that includes those domains that are expected to be impacted the most. The researcher will give the identical questionnaire both pre- and postintervention and will demonstrate that the intervention was successful. But the changes may be due to concurrent events and not to the intervention itself. Moreover, the new index is rarely transferable across time and conditions.

In 1996, the Psychosocial Impact of Assistive Devices Scale (PIADS) was produced. This is a 26-item generic questionnaire designed to measure the impact of AT devices in terms of three generally accepted QOL factors, *competence, adaptability,* and *self-esteem.* A number of studies

have demonstrated that the PIADS is a reliable, valid, and responsive measure of a variety of AT devices (e.g., eyeglasses, electronic aids for daily living, and mechanical ventilators). One finding is that the impact on QOL remains stable over time, and, in a number of studies, significant differences on the QOL factors were found between retainers and abandoners of AT devices, leading to the prediction of abandonment of various AT.

Abandonment

There is a great deal of dissatisfaction among AT adopters with currently prescribed ATs. Simple ones, such as contact lenses, are abandoned at a high rate (up to 50%), hearing aids and wheel chairs are frequently traded in for other models, and even mechanical ventilators are sometimes abandoned by a PWD with no alternative but death. The reasons for abandonment are many and have been studied recently by a growing number of psychologists.

The most common reason for abandonment is that the device or program is not flexible for a PWD who is undergoing change. For example, a person using a walker may lose more control over his or her gait and is forced to adopt a wheelchair instead of the walker, or someone wearing eyeglasses may resort to laser surgery that results in abandonment of the AT because the person's vision has now improved. But many other reasons for abandonment can be identified that are specific to the AT and the individual's interaction. Although early research focused mainly on the physical properties of the AT device, more recently the direction has shifted to looking also at person variables and the fit between the two, termed the Matching Person and Technology Model, designed to measure satisfaction, including the motivational, personality, gender, and psychosocial factors that affect this fit. A number of questionnaires are now available to measure satisfaction of consumers with ATs as an outcome variable. While concerned with satisfaction derived from adopting an AT, they focus directly on positive and negative aspects of the psychosocial life of the consumer and attempt to account for the high rate of dissatisfaction.

ASSOCIATION FOR BEHAVIOR ANALYSIS

The Association for Behavior Analysis (ABA) is an organization that includes psychologists, educators, behavioral health practitioners, and practitioners working in other settings (e.g., the private sector) whose scholarly activities and practice derive from the seminal work of psychologist B. F. Skinner (e.g. 1938, 1953, 1974). Its mission is to "develop, enhance, and support the growth and vitality of behavior analysis through research, education, and practice." There are 3,922 members, of whom 1,212 are full members, 1,412 are student members, and 1,006 are associate members. Those remaining are chapter-adjunct or emeritus members. The association has 39 affiliated chapters, including 15 international chapters. Members of ABA are located in 41 countries around the world.

History

ABA was incorporated in 1974, the year in which it held its first annual meeting, which was in Chicago, Illinois. In 1978, ABA added the subtitle "An International Organization" to its name in response to a growing membership from countries outside the United States. In 1980, the Society for the Advancement of Behavior Analysis was created to provide foundational support to ABA. The immediate past president of ABA serves as president of the Society. ABA's central office was housed on the campus of Western Michigan University from its inception until 2002, when it moved to ABA's own building in Kalamazoo, Michigan.

The members of the original 1974 organization committee (which later became the executive council) were Sidney Bijou, James Dinsmoor, Israel Goldiamond, Bill Hopkins, Neil Kent, Kenneth Lloyd, Richard Malott, Gerald Mertens, Jack Michael, Roger Ulrich, and Scott Wood (Peterson, 1978).

Since its founding, ABA has held an annual convention in cities across the United States and in Canada. In November 2001, it sponsored its first international meeting, in Venice, Italy.

Membership

There are several classes of membership, including full membership in ABA, which requires (1) a master's degree in experimental or applied behavior analysis or a related field, and (2) contributions to the field of behavior analysis; affiliate membership, which is designed for persons who have an interest in behavior analysis or who have completed undergraduate credit but do not meet full member requirements; student membership, which is for full-time undergraduate or graduate students, residents, or interns; chapter-adjunct membership, which allows members of affiliated chapters to join ABA; supporting or sustaining membership, which is for full members of ABA who support the organization financially through higher dues; and emeritus membership, which is for voting members who have retired.

Governance and Organization

The organization is governed by an executive council comprised of seven members elected by the full (voting) mem-

bership at large; an international representative, elected by international voting members; and a student representative, elected by the student members. The council members reflect the diverse interests of the membership in that one council member is elected to represent each of the following interests: the international community, applied behavior analysis, and the experimental analysis of behavior. There also are two elected members-at-large. The other elected members of the council are the immediate past president, the president, and the president-elect. Presidents thus serve a 3-year term on the council and serve as president of the organization for 1 year.

The executive council oversees the work of a number of boards, each with committees and special-purpose task forces that represent the diverse interests and concerns of the organization. The boards are the Science Policy and Research Board; the Education Board; the Standards, Accreditation, and Professional Affairs Board; the Affiliated Chapters Board; the Membership Board; the Program Board; and the Publication Board.

The ABA is administered by an executive director and a staff at its central office in Kalamazoo.

Association Activities and Their Impact

The activity with the most visible impact is ABA's annual convention, which attracts more than 2,800 behavior analysts, who attend workshops, invited addresses, symposia, round-table discussions, addresses, and poster sessions on a range of topics relevant to the advancement of the basic science of behavior, and to the application of behavioral principles, in a variety of settings with a number of different populations. Continuing education credit for both psychologists and behavior analysts is available during the convention. ABA sponsors an annual award series, with the recipients recognized at the annual convention, to acknowledge distinguished contributions both to the discipline of behavior analysis and to the dissemination of behavior analysis among both professional and lay audiences.

In addition to the annual convention, ABA is the leading advocate in the United States for the efficacy of behavior analysis and behavioral psychology in applied settings. This advocacy takes several forms, including legislative-influence efforts, programs of public education, and support of the Behavior Analyst Certification Board (BACB), the national certification organization for behavior analysts, designed to ensure the quality of individuals offering their services in both the public and private sector as behavior analysts. Certification of individual members as Certified Behavior Analysts requires an advanced degree relevant to behavior analysis and the passing of a written and oral certification examination administered by the BACB.

To complement the BACB certification program for individual behavior analysts, ABA helps assure the quality of educational programs offering training in behavior analysis. Through its accreditation program, both doctoral and master's-level training programs can be accredited by ABA by meeting a set of requirements. Such accreditation involves a self-study by the applicant program, followed by a formal visit to the program by representatives of the accreditation committee. Approval of the program's accreditation is decided by the executive council.

Leadership and support are provided to the academic community in other ways as well. For example, ABA is a member of the Federation of Behavioral, Psychological, and Cognitive Sciences, an organization of scientific societies that supports research in the disciplines represented by the member societies. This support takes the form of efforts to educate and impact the legislative branch of the federal government and such federal agencies as the National Institutes of Health and the National Science Foundation.

Two professional journals are published by ABA: *The Behavior Analyst* and *The Analysis of Verbal Behavior.* The former publishes both scholarly articles and articles on professional issues relevant to the general discipline of behavior analysis, and the latter publishes articles relevant to the understanding of language, in the tradition of B. F. Skinner's (1957) book *Verbal Behavior,* from a behavior-analytic perspective.

ASSOCIATIONISM

Association of ideas is the intuitive notion that ideas are grouped together, or associated, in explicable ways. For example, if someone says "horse," one is likely to think "animal," "rider," or "race," but not "shelf," "battery," or "floor." The first set of ideas are all associated with horses, the latter are not. Associationism embraces association of ideas and turns it into a general systematic account of mind or behavior.

John Locke coined the phrase "association of ideas" in the fourth edition of his *Essay Concerning Human Understanding.* He regarded associations as a kind of "madness,"

as they get in the way of rational, directed thinking. Notwithstanding Locke's condemnation, several eighteenth-century philosophers turned association of ideas into associationism, a view of mind and behavior that places association at the heart of thinking and tends to reduce all psychological principles to the principle of association.

Foremost among these philosophers were David Hume and David Hartley. Hume proudly reduced the mind to the association of ideas, maintaining that the mind contains either perceptions or their copies and ideas, and that ideas are glued together by two laws of association, similarity and contiguity (whereby two ideas that occur together become linked).

The tendency signaled by Hume and Hartley to elevate the principle of associative learning was continued by the nineteenth-century British associationists James Mill, his son John Stuart Mill, and his son's friend, Alexander Bain. James Mill proposed a mechanical theory of association in which ideas are stuck together like tinkertoys. J. S. Mill recognized the unwieldiness of this arrangement and proposed mental chemistry, in which several ideas can merge into one and reveal emergent properties, as when hydrogen and oxygen merge to make water. Bain placed Hartley's project on a better foundation, uniting association philosophy with up-to-date physiology to produce a real association psychology.

It was then only a short step to psychological experiments on association formation, or learning and memory. Thomas Brown had already put forward an empirically researchable form of associationism in his secondary laws of association, which further specified the operation of the primary laws (contiguity, similarity). For example, Brown argued that the more frequently two ideas were contiguously experienced, the stronger would be the associative bond between them, but this law of frequency is open to empirical test.

In the twentieth century, association of ideas transmuted into association of stimulus and response under the influence of behaviorism. The laws of association became the laws of learning; the law of frequency became the gradually rising learning curve; the law of similarity became the generalization gradient; and contiguity of ideas became the contiguity of unconditioned and conditioned stimuli. More recently, eighteenth-century concepts have revived with cognitive psychology, which views memory as an associative network of ideas (e.g., in J. R. Anderson and G. H. Bower's *Human Associative Memory*) embedded in a complex information-processing system, rather like the old mental faculties.

The doctrine of association has not gone unchallenged. The Gestalt psychologists completely renounced it, and various psychologists have periodically attacked it. Nevertheless, association of ideas has proven the most durable of psychological concepts, having maintained an unbroken record of influence from Plato to cognitive science.

ATHLETIC COACHING

At all levels of sport, coaches function as educators, leaders, and strategists. In these roles, they can strongly influence the performance and personal development of the athletes with whom they come in contact. The teaching techniques coaches employ, the goal priorities they establish, the values they exhibit and reinforce, and the relationships they form with athletes have all been topics of psychological research.

One important area of research is coach instructional techniques. Behavioral researchers have observed and analyzed the techniques employed by outstanding coaches at all levels of competition. They have found that such coaches tend to use approaches that have proven successful in enhancing performance in other performance domains, such as education and business. Systematic goal setting has proven to be a powerful technique for positive skill development. Coaches who employ this technique analyze the task requirements and current skills of the athlete, set specific behavioral (not outcome) goals, develop individualized action plans for developing the needed skills, set timelines for attainment, and closely monitor the targeted behaviors to assess change. This approach has proven effective from youth sports to the professional level. Other research has shown that behavioral feedback and the use of positive reinforcement enhance the development of sport skills. In general, a positive approach to strengthening desired behaviors through encouragement, sound technical instruction, and positive reinforcement of desired behaviors is preferred by athletes to a negative one featuring criticism, punishment, and an emphasis on avoiding mistakes. Athletes expect coaches to exert control and maintain discipline, but they prefer that it occur within the context of a basically positive coach-athlete relationship.

Much research has focused on youth-sport coaches in recent years. Behavioral coding techniques have been developed, enabling researchers to observe coaches during practices and games, assess their responses to particular classes of situations (e.g., positive and negative athlete behaviors and game developments), and generate behavioral profiles of the coaches based on thousands of their behaviors. They can also obtain athletes' and coaches' ratings of how often the coach engaged in the various behaviors that were coded. Such research has shown that even child athletes are more accurate perceivers of coaching behaviors than are the coaches themselves. Studies have also shown that coaching behaviors are more strongly related to athletes' attitudes toward the coach than are won-lost records. Although winning becomes more important in adolescence than at earlier ages, behaviors continue to be more powerful predictors of athletes' evaluations of coaches and desire to play for them again. In line with the positive approach described above, coaches who create a supportive environment through their use of encouragement, technical instruction, positive reinforcement of desired athlete behav-

iors (including compliance with team rules), and avoidance of punitive behaviors are best liked by athletes. On teams coached by positive coaches, athletes also like their teammates more, possibly because of the socially supportive atmosphere encouraged and modeled by the coach.

Such findings have inspired a number of coach-training programs designed to help coaches create an athletic environment that is enjoyable and that fosters positive psychosocial outcomes. Such programs give coaches specific behavioral guidelines, show them how to engage in the positive behaviors and find alternatives for punitive ones, and often teach coaches how to monitor their own behavior to make them more self-aware. Although most of these programs have not been formally evaluated, one program, Coach Effectiveness Training (CET), has yielded encouraging results. Behavioral observations and athletes' ratings of their coaches' behaviors indicated that, compared with untrained coaches, those trained in CET behaved in a more supportive and encouraging manner. Although their teams did not win more games, the trained coaches were evaluated more positively by their athletes, and their athletes showed significant increases in self-esteem and decreases in performance anxiety by the end of the season. They also showed a lower rate of dropping out of sports the following season (6% attrition rate compared with a 27% dropout rate among athletes who played for untrained coaches). The latter finding is important because research also shows that children and adolescents who remain involved in sports are less likely to engage in delinquent and other self-defeating behaviors.

An important focus of current research is the motivational climate created by coaches. Analyses of achievement-related goals in children and adults have identified two important goal orientations, known as task- and ego-orientation. Task-oriented people feel successful and competent when they have learned something new, witnessed skill improvement in themselves, mastered the task at hand, or given their best effort. In contrast, ego-oriented people feel successful when they demonstrate superiority over others or avoid feeling inferior to others. Although both orientations can lead to successful performance, research in educational and sport settings indicate that task-oriented people place relatively more emphasis on effort than outcome, are more likely to persist in the face of adversity or failure, and select more challenging goals. They can feel successful even when the desired outcome has not been attained, if they believe that they gave maximum effort and learned important things from the experience. Ego-oriented individuals show less persistence in the face of adversity and are more likely to experience distress and eventually avoid settings in which they do not win out over others.

Most people have both task- and ego-orientations to varying degrees. The situational context or motivational climate that exists in achievement settings can differ in the extent to which task- or ego-involving goals are emphasized. A mastery-oriented motivational climate supports and strengthens task orientation; an ego-oriented climate fosters competitiveness and comparisons with others. Much educational research has shown that mastery-oriented climates promote higher academic performance and intrinsic learning motivation, as well as lower levels of fear of failure. This research is now being applied within the athletic domain by encouraging coaches and parents to establish a mastery-based motivational climate. The principle is that if athletes are oriented toward becoming as proficient as possible ("their" best rather than "the" best), are not shackled by fear of failure, and are prepared and technically well-coached, winning will take care of itself within the limits of their ability. Research shows that mastery-oriented sport environments provide more enjoyable and fulfilling settings for the majority of athletes. More importantly, the lessons learned in mastery environments may have salutary carryover to other achievement domains as well.

ATTACHMENT STYLES

Observational studies of parent-child bonding revealed the existence of four distinctive styles of relational behavior exhibited by infants in distress. Further research conducted with older children, adolescents, and adults has supported the ongoing development of similar response styles across the lifespan. These *attachment styles* classify the majority of individuals as *secure* and specify three varieties of *insecure* or *anxious* attachment patterns. Individuals classified as *securely attached* consistently demonstrate superior levels of psychosocial adjustment across a variety of domains when compared to people classified into one of the three insecure categories.

Attachment Theory

British psychoanalyst John Bowlby (1958, 1969), strongly influenced by ethological theories of primate evolution, formulated *attachment theory* to explain how selection pressures supported the survival of offspring whose behavior elicited and maintained maternal protection. He further theorized that early attachment experiences generate *internal working models* that encode aspects of relational behavior and expectations.

Empirical support for attachment theory later emerged in Ainsworth's observational studies of *separation anxiety.* She and her collaborators (Ainsworth, Blehar, Waters, & Wall, 1978) were the first to classify children's attachment styles based upon each child's behavior during a series of

separations and reunions with that child's mother. These original attachment styles were labeled *secure, avoidant,* and *resistant/ambivalent.* A more recently accepted attachment classification, termed *disorganized/disoriented* (Main & Solomon, 1986), was created to capture the behavior patterns of children who fit poorly into the other attachment categories.

More recently, attachment theory has been extended as a broad explanatory framework for understanding close personal relationships in adulthood (Hazan & Shaver, 1987). However, as the applications of attachment theory are increasingly extended, there is a danger that its principles will be distorted to fit so many aims that a corresponding loss of coherency will result.

Typology of Child and Adult Attachment Styles

Infants whose signals of distress consistently receive nurturing care tend to develop a style of responding well to soothing behavior from others. Such children appear to expect nurturance and demonstrate a balance of exploratory interest in their environment and reliance upon the caregiver as a secure base in times of insecurity or distress. The attachment style of children fitting this description is designated as *secure.* Adults who are comfortable with depending on others and having relational partners depend on them are considered to exhibit a secure *adult attachment pattern.* Patterns of attachment behavior at any age that deviate substantially from this model are characterized as *anxious* or *insecure.*

Anxious attachment styles have been defined by various terms including ambivalent, avoidant, and disorganized/disoriented among children and preoccupied, dismissive, and fearful among adults. Children who seldom seek parental care and who may even show somewhat more interest in the attention of adult strangers are classified as *avoidant.* The corresponding style of adults who adopt an extremely self-reliant attitude and who express little interest in close relationships with others is termed *dismissive.* If the person's attitude toward relationships contains evidence of both devaluing relationships and showing distrust toward partners, the *fearful* attachment classification is indicated.

Some children heartily protest the absence of their caregivers but are difficult to soothe when their signals of distress are responded to. This style of anxious attachment is classified as *ambivalent* because the child appears to relate to the parent as alternately desirable and aversive. When adults perceive relationships as highly desirable, but seem prone to anxious concerns about rejection or require excessive reassurance from their partners, they are likely to be classified as exhibiting a *preoccupied* attachment style.

Children who display idiosyncratic and contradictory sequences of attachment responses have been termed *disorganized/disoriented.* These children may appear confused and lacking a coherent strategy for obtaining and maintaining comfort and protection. Measures of adult attachment are likely to classify such individuals under the *fearful* attachment style.

Methods of Assessing Attachment Styles

While the classification of attachment in infants is still conducted almost exclusively by means of the *strange situation test,* a variety of interviews and self-report measures are now employed to assess attachment styles in adults. The Adult Attachment Interview (George, Kaplan, & Main, 1985) is the most prominent example of the interview approach. Researchers needing measures that lend themselves to use with larger samples have developed self-report measures yielding various indices of attitudes and reactions in close, personal relationships.

Early examples of this method included the three-category approach of Hazan and Shaver (1987) and the four-category approach of Bartholomew and Horowitz (1991). Later developments of similar measures have departed from categorical assignment and allowed individuals to rate the degree of correspondence between themselves and each of the attachment style prototypes. These scores could then be combined to develop a more complex picture of individual differences in adult attachment styles.

An alternative innovation has been to construct multi-item self-report measures consisting of statements about oneself in relational contexts. This method improves the reliability of the measures, and the items are sorted according to various theoretical dimensions that have received support in factor-analytic studies. Extensive analyses performed on both categorical and dimensional measures of attachment (Fraley & Waller, 1998) supported the conceptual and empirical superiority of the dimensional approach.

Implications of Attachment Styles for Social Adjustment

Insecure attachment in early childhood predicts a variety of undesirable outcomes, including poor peer relationships, difficulties in regulating negative affect, and impulsive, aggressive, and disruptive behavioral patterns. Moreover, maltreatment in childhood has been consistently shown to be a risk factor for the development of insecure attachment styles.

Adolescents and adults with insecure patterns of attachment exhibit higher rates of affective disorders, anxiety disorders, and personality disorders than securely attached peers. Insecure attachment has also been implicated as a risk factor for poor relational quality in marriage and other intimate relationships (Kobak & Hazan, 1991).

ATTITUDES

Throughout the history of social psychology, the attitude construct has played a central role in the explanation of social behavior. Attitude is defined as a disposition to respond favorably or unfavorably to an object, person, institution, or event. An unobservable, hypothetical construct, attitude must be inferred from measurable responses that reflect positive or negative evaluations of the attitude object. People can be asked to express their attitudes directly, by judging the object of the attitude as *good* or *bad* or by rating their degree of liking for it. Alternatively, attitudes can be inferred more indirectly from *cognitive responses* or beliefs (reflecting the individual's perception of and information about the attitude object); *affective responses* (feelings toward the object); and *conative responses* (behavioral intentions, tendencies, and actions with respect to the object). For example, attitudes toward an ethnic group can be inferred from beliefs (whether valid or biased) that attribute certain traits, abilities, opinions, and lifestyles to members of the group in question; from such affective or emotional responses as expressions of admiration or contempt for the ethnic group; and from intentions or overt actions that reflect tendencies to approach or avoid members of the group under consideration.

Although people are generally aware of their attitudes, research has shown that conscious or *explicit* attitudes can be accompanied by evaluatively discrepant *implicit* attitudes. Thus, when well-established attitudes change, the old implicit attitude is not necessarily replaced but may coexist with the new explicit attitude, and for such socially sensitive topics as racial prejudice, an explicit liberal or egalitarian attitude toward a minority group can coexist with a more negative implicit stereotype. Subtle response latency measures are used to uncover such implicit attitudes.

Attitude Formation

Functional Approach

Early attempts to identify the origins of attitudes focused on the needs or functions they may serve. Thus, attitudes were assumed to have instrumental or utilitarian functions (helping people attain rewards and avoid punishments); knowledge functions (organizing and simplifying people's experiences); expressive functions (enabling emotional release); and ego-defensive functions (protecting and enhancing the self). Although it generated considerable interest, the functional approach to attitudes has produced only a modest amount of research and has been of limited practical value.

Behavioral Approach

Behaviorally oriented social psychologists have used principles of classical conditioning to describe and explain attitude formation. Repeated and systematic association between the attitude object (conditioned stimulus) and a positively or negatively valued event (unconditioned stimulus) is assumed to produce a favorable or unfavorable implicit reaction (attitude) to the object. Controversy revolves around the question of awareness—the extent to which awareness of the object-event contingencies is a necessary requirement for conditioning of attitude. Although the issue has not been completely resolved, few studies have clearly demonstrated automatic conditioning of attitude without contingency awareness.

Cognitive Approach

A general trend toward cognitive or information-processing explanations of social behavior has brought a concomitant decline in the importance accorded to needs and automatic conditioning processes. Instead, stress is now placed on the role of information as a basis of attitude formation. According to this view, beliefs—representing people's subjective knowledge about themselves and their world—are the primary determinants of attitudes. Each belief links the attitude object to a positively or negatively valued attribute; thus smoking (the object) causes lung cancer (the attribute). Generally speaking, the greater the number of be-

liefs that associate the object with positive attributes, and the smaller the number of beliefs that associate it with negative attributes, the more favorable is the resultant attitude toward the object.

Attitudes and Behavior

Because attitudes are considered to be behavioral dispositions, it is natural to assume that they direct, and in some sense determine, social action. However, by the late 1960s there was growing evidence that a strong relation between verbal expressions of attitude and overt behavior could not be taken for granted. Controlled studies failed to find relations between racial attitudes and such actions as accepting members of the racial group in a hotel or restaurant, conforming with their views or behaviors, or extending an invitation to members of that group; attitudes toward cheating failed to predict actual cheating behavior; attitudes toward another person were unrelated to cooperation or competition with that person; work-related attitudes had little to do with absenteeism, tardiness, or turnover; and so forth.

Under the weight of this negative evidence, social psychologists were forced to reexamine the nature of attitude and its relation to social behavior. It was concluded that a strong relation between verbal and overt actions can be expected only if the two types of responses are compatible with each other in terms of their generality or specificity. Thus, although unrelated to any single action, verbal expressions of general liking or disliking for an ethnic group are found to be strongly related to aggregate measures of discriminatory behavior that involve different actions toward various members of that group, observed in different contexts and on different occasions. By the same token, degree of religiosity often fails to predict single church-related activities, but it is strongly related to religious behavior that aggregates across different types of religious activities, contexts, and occasions.

Single behaviors, on the other hand, can be predicted from attitudes toward the behaviors themselves—for example, attitudes toward smoking marijuana (rather than global attitudes toward the counterculture), attitudes toward attending church services (as opposed to attitudes toward the church), or attitudes toward donating blood (instead of global attitudes concerning altruism). However, response tendencies reflected in attitudes toward specified actions can change as a result of situational demands or unanticipated events. Moreover, individuals vary in their susceptibility to the influence of such external factors. Thus, while attitudes toward behaviors tend to produce corresponding behavioral intentions, the extent to which these intentions are actually carried out is moderated by situational factors and individual difference variables. Nevertheless, barring unforeseen events, behavioral attitudes and intentions are usually found to be quite accurate predictors of subsequent actions.

ATTRIBUTION THEORY

Consider questions such as “Why did I fail my exam?” “Why won’t Mary go out with Jim?” “Did he hit me on purpose?” Attribution theory refers to a set of propositions and hypotheses regarding how laypersons arrive at answers to these questions and what the consequences are of their causal beliefs. Philosophers including Hume, Kant, and Mill, who have guided some attributional thinking, have written extensively about questions of causality. However, they address these issues logically and prescriptively rather than describing how the layperson arrives at a causal understanding. In addition, philosophers have not been interested in the psychological importance and functions of perceptions of causality, whereas these concerns are central to attribution theorists.

The originator of attribution theory, Fritz Heider, primarily introduced his ideas in the 1950s. Attributional thinking then reached its zenith in the 1970s, when it was the dominant topic in social psychology and influenced clinical, educational, motivational, and personality psychology as well. In that era, the ideas of Edward Jones, Harold Kelley, Bernard Weiner, and others supplemented the thinking of Heider and, to some extent, moved away from the focus on naive psychology.

Reaching Causal Inferences

One goal of attribution theorists has been to identify the personal and situational determinants of causal understanding. It has been assumed that humans want to attain a cognitive mastery of their world. Further, people are regarded as naive scientists, logical and rational—albeit not infallible—and subject to systematic biases and errors. The following discussion introduces a few specific research directions and some empirical findings regarding causal inferences.

In the desire for understanding, it has been documented

that causal search is not undertaken in all instances but is most likely given an important, unexpected, and negative event or outcome. This might be failure at a crucial exam, rejection of a marriage proposal, and the like. Principles found in covariation analyses regarding the presence and absence of causes and effects are important sources of causal information to help determine the answers to "why" questions. For example, failure at an exam is more likely to be self-attributed if there have been many prior personal failures and knowledge of the successes of others. In addition, causal rules are used such that, for example, if beliefs of multiple causality are elicited, then even in the presence of insufficient effort there will be additional attributions to lack of ability or to some environmental factors as causes of the failure. Further, the presence of some causes may result in other causes being discounted. One controversy associated with the latter process concerns the hypothesis that rewarding pupils for successful achievement performance reduces their motivation because the extrinsic reward results in a discounting of their intrinsic interest.

It also has been reasoned (again, with controversy) that the behavior of others tends to be ascribed to a stable disposition or trait inasmuch as explanations that capture enduring aspects of the world often are preferred, and the other is dominant in social perception. The underestimation of the situation as a perceived cause of the behavior of others and overattribution to the person has been labeled "the fundamental attribution error." This principle has been challenged in cross-cultural research, for it has been argued that situational attributions are more salient among Asians.

Another bias that has been documented in attribution research concerns beliefs about the causes of positive and negative events. Self-attributions tend to be given for positive outcomes ("I succeeded because I studied hard"), whereas negative outcomes elicit external attributions ("I failed because the exam was unfair"). This pattern of attributions has been labeled the "hedonic bias" inasmuch as positive self-directed emotions and the maintenance of self-esteem are fostered.

Consequences of Causal Beliefs

The research concerning the consequences of perceived causality is less voluminous than that associated with the reaching of causal inferences, but it nonetheless is very substantial, particularly in disciplines other than social psychology. Here, again, only a small sample of the research directions is presented.

In the field of clinical psychology, it has been suggested that ascribing negative events to something about the self that also is not subject to personal control produces a state of "learned helplessness," which promotes and/or accompanies depression. Hence, failure perceived as due to lack of aptitude may be an antecedent (or correlate) of depression. Attribution-guided research within clinical psychology also has revealed that when the behavior of a mentally ill family member is ascribed to a cause under personal control ("He is just being lazy")—in other words, when the cause implicates personal blame—then the likelihood increases that the ill person will return to institutionalization because of the negative emotions this elicits among family members.

Assignment of responsibility and blame is central in many other contexts as well, suggesting that in addition to being naive scientists, humans also act as naive judges. Other-blame, which is one indicator of marital distress, also is elicited by a variety of stigmas, including alcoholism and obesity, and decreases help giving. The anticipation of the negative consequences of being perceived as responsible gives rise to a variety of impression-management techniques that deflect this inference. For example, students publicly claim lack of ability rather than low effort as the cause when explaining their failure to authority figures (but not when ascribing the cause of failure to peers).

Adaptive and maladaptive attributions also have been identified in studies of coping with stress. Following a negative life stressor, such as rape, individuals ascribing this event to their character ("I am a risk taker") do not cope as well as those attributing the event to a particular behavior ("I accidentally was in the wrong place at the wrong time").

Individual differences in coping with aversive circumstances are linked with disparate beliefs about the perceived causes of negative events. For these reasons, attributional therapies have been devised that attempt to change causal beliefs so they are more adaptive.

In sum, causal beliefs play an important role in self- and other-understanding and significantly influence emotions and subsequent actions. The study of causal attributions therefore provides one of the foundations for social psychology and also has great relevance for other subareas within psychology.

Bernard Weiner
University of California, Los Angeles

AUTOMATIC THOUGHTS

Automatic thoughts are spontaneous ideas—ideations or thoughts typically indicated by internal self-statements or self-talk. Cognitive theories emphasize the roles of belief systems, cognitive schematas, intellectual processes, and automatic thoughts in behavioral operations. Each individual has a frame of reference, variously called personality, lifestyle, worldview, and so on, within which one copes with life. One's inner belief structure depends on past experiences, learnings, goals, purposes, and core belief structures. Automatic thoughts differ from belief structures. Merluzzi and Boltwood (1989) state, "an important distinction between automatic thoughts or self statements and

underlying schemata or belief systems [is] automatic thoughts are spontaneous self statements or ruminations. . . . In contrast cognitive schematas are seen as relatively stable, enduring traits like cognitive patterns" (p. 256). Similarly, Beck and Weishaar (1989b) distinguish between automatic and voluntary thoughts. Voluntary thoughts are fully conscious self-determined decisions. Automatic thoughts "are more stable and less accessible than voluntary thoughts [and] are generally quite powerful" (Beck & Weishaar, 1989a, p. 28). Both voluntary thoughts and automatic thoughts are consistent with one's core beliefs or schematas.

Beck and Weishaar (1989b) point out that a variety of situations, events, or circumstances may trigger underlying core beliefs and generate automatic thoughts. More specifically, automatic thoughts "intercede between a stimulus event and one's emotional and behavioral reactions to it" (Beck & Weishaar, 1989a, p. 28).

Unconscious Processes

Automatic thoughts are considered to be unconscious or lying below the surface of immediate conscious awareness. They are spontaneous self-statements, stemming from core beliefs out of conscious awareness.

Applications

Use of automatic thoughts in psychology center on changing belief systems through psychotherapy. In cognitive and cognitive-behavioral therapies, the primary focus is on changing the client's "distorted" or dysfunctional belief systems. Client's belief systems are explored and accessed. Albert Ellis outlines 12 irrational beliefs (Criddle, 1975), and Beck outlines primarily six cognitive distortions or distorted thoughts—belief processes (Beck & Weishaar, 1989a, 1989b). Others have added to and modified irrational beliefs and cognitive distortions (McMullin, 1986).

Core beliefs can be accessed by having people monitor their own spontaneous self-statements or automatic thoughts. These are then challenged and changed. Therapy problems can be resolved by changing one's views of the problems via automatic thoughts, a kind of paradigmatic shift in thinking, known in psychotherapy jargon as *reframing*.

AUTORECEPTORS

Autoreceptors are defined as receptors located on neurons that release a transmitter that activates such presynaptic receptors. They may be located on the neuronal cell body and/or the nerve terminals. In general, they exert a negative feedback influence on the function of their neuron. That is, when overactivated by their neurotransmitters, an inhibitory influence is triggered. Autoreceptors are determinant in controlling the function of neurons. Under most physiological conditions, they are tonically activated. This can be put into evidence by the administration of an antagonist, which will increase neuronal output. Using exogenous agonists, it is sometimes possible to obtain, upon their maximal activation, a complete shutdown of the neuronal process to which they are coupled. They have, therefore, been targets for drug development. The scope of this brief synopsis is to review some neuronal systems for which autoreceptors have been clearly identified and for which selective ligands have been developed for actual or potential therapeutic use.

Noradrenaline Autoreceptors

Noradrenaline (NE) neurons are endowed with autoreceptors on their cell bodies, where they exert a negative feedback role on firing rate. They are of the α_{2A} subtype as confirmed by genetic cloning experiments. Such autoreceptors are also located on NE terminals throughout the brain, where they inhibit the release of NE. The prototypical agonist of such receptors is clonidine, which is commercialized mainly for the treatment of high blood pressure. Its hypotensive effect would not, however, be exclusively mediated by its action on autoreceptors as α_2-adrenoceptors are also located postsynaptically. Yohimbine, among several agents capable of blocking α_2-adrenoceptors, is a relatively selective agent used mainly to treat erectile dysfunction. The antidepressant drugs mirtazapine and mianserin antagonize α_2-adrenoceptors, leading to enhanced NE release that contributes to their therapeutic actions in major depression. While mirtazapine acts in part by enhancing indirectly the activation of excitatory α_1-adrenoceptors located on serotonin (5HT) neurons, mianserin antagonizes α_1-adrenoceptors.

Serotonin Autoreceptors

As for NE neurons, 5HT neurons are endowed with cell body and terminal autoreceptors that exert a negative feedback influence on neuronal firing and release, respectively. The somatodendritic ones that inhibit firing rate are of the $5HT_{1A}$ subtype, and the ones located on terminals are mainly of the $5HT_{1B}$ subtype. The former subtypes of autoreceptors play a crucial role in the antidepressant effect of 5HT reuptake blockers and monoamine oxidase inhibitors because they desensitize after 2 to 3 weeks of treatment. This permits a recovery of the firing rate of 5HT neurons to normal in the presence of inhibited reuptake or monoamine oxidase inhibition, then producing a net increase in neurotransmission. The time course for this recovery in firing activity is consistent with the onset of the therapeutic action of such drugs in major depression. This observation has recently been put to clinical use by accelerating the antidepressant response of such drugs with the $5HT_{1A}$ autoreceptor antagonist pindolol. Eight of the first ten placebo-controlled studies documented a 7- to 14-day acceleration with this strategy.

There are $5HT_{1D}$ autoreceptors at the level of the cell body of 5HT neurons that exert an inhibitory role on 5HT release in the midbrain and thus, indirectly, on terminal 5HT release through a $5HT_{1A}$ autoreceptor interaction. Finally, $5HT_3$ receptor activation, under certain experimental conditions, enhances 5HT release and was prematurely attributed to an autoreceptor function. Subsequent experiments have, however, revealed that these receptors are not located on 5HT neurons and, until proven otherwise, should not be considered autoreceptors.

Dopamine Autoreceptors

Dopamine neurons have autoreceptors of the D_2 subtype located on their soma and dendrites. When activated by dopamine itself or by exogenous D_2 agonists, such as apomorphine, neuronal firing is attenuated. On the contrary, their antagonism with the prototypical antipsychotic drug haloperidol leads not only to an increased firing rate but also to a discharge pattern characterized by bursts that produce a greater release of dopamine than would the same number of action potentials occurring at regular intervals. Prolonged D_2 antagonism leads to a depolarization of these neurons and thus a shutting off of their firing activity. Such a silencing of the mesolimbic-dopamine neurons likely plays an important role in mediating the antipsychotic response because it leads to a decrease of dopamine in postsynaptic structures, contributing to decreased dopamine neurotransmission. Because long-term administration of the atypical antipsychotic agent clozapine depolarizes mesolimbic-dopamine neurons without affecting substantia-nigra-dopamine neurons, which give rise to projections to the striatum, this differential activity may account for the lack of movement disorders of clozapine. In support of this possibility, typical antipsychotic agents such as haloperidol, which produce such extrapyramidal side effects, depolarize both populations of dopamine neurons.

Other Chemospecific Neurons with Autoreceptors

Cholinergic terminals have inhibitory receptors of the muscarinic 2 subtype, which exert a negative feedback influence on release. Considerable evidence also exists for nicotinic receptors exerting a positive influence on acetylcholine release. As acetylcholine is a key neurotransmitter in Alzheimer's disease, these two types of receptors represent targets for the development of drugs to enhance acetylcholine release from the remaining fibers, that is, muscarinic type 2 antagonists and nicotinic agonists.

Glutamatergic terminals have autoreceptors of the metabotropic subtype 2 that, when overactivated, attenuate glutamate release. Recently, agonists have been developed in the hope of helping treat conditions such as opiate withdrawal symptoms, given that this condition increases glutamatergic activity that stimulates NE activity. Indeed, this condition cannot be controlled using only the α_2-adrenergic agonist clonidine to attenuate physical and psychological agitation.

GABA neurons inhibit the release of their own neurotransmitter via $GABA_B$ autoreceptors. However, the exact role that the GABA agonist baclofen exerts on these autoreceptors to mediate the antispasmodic effect of this drug in patients with spinal cord lesions remains to be clarified.

Finally, histamine neurons bear autoreceptors of the H_3 subtype that inhibit histamine release. Although selective H_3 antagonists have been developed and demonstrated to increase arousal and decrease food intake in animals, they have not yet reached the therapeutic armamentarium. They are interestingly devoid of peripheral side effects because H_3 receptors are virtually absent outside the central nervous system.

In summary, autoreceptors are crucial neuronal elements because they are intimately involved in modulating the overall function of their neurons. As for most types of neurons, their presence probably represents more the rule than the exception. They have been exploited in human therapeutics using either agonists, mainly to decrease neurotransmitter release, or antagonists, to promote neuronal output. Their discovery and characterization have already led to advances of certain disorders and should yield further therapeutic indications in the future.

AUTOSHAPING

Autoshaping refers to the process whereby biologically primed stimulus-response relations interact with and occasionally override operantly learned, potentially incompatible response-reinforcer relations. It may also be referred to as *misbehavior of organisms.* The name is derived from quick operant shaping (i.e., automatic shaping) that occurred without apparent reinforcement of successive approximations. Typically, the behavior observed depends upon the object or goal received. For example, food appears to release eating behavior and water appears to release drinking behavior. Although initially thought to manifest only among simpler mammals, autoshaping may occur in humans (Siegel, 1978). Consensus regarding etiology is lacking, though this is not a result of irregularities in data; the phenomenon of autoshaping is valid and reliable.

Example

Pigeons quickly learn key pecking responses when a key is illuminated and provides a reliable and salient cue for the delivery of food (Brown & Jenkins, 1968). However, attempts to operantly extinguish or negatively punish pecking generally fail, leading one to question whether the behavior was acquired through operant training or some other modality.

Theories of Autoshaping

Autoshaping resides in the gap between nature and nurture. It has been posited that autoshaping represents interactions between organism and environment, phylogeny and ontogeny, and respondent and instrumental processes. Each of these represents a different level of analysis to the puzzle of autoshaping.

Though the formal study of autoshaping largely began in the late 1960s, the existence of the phenomenon may have been foreshadowed by Darwin's theory of evolution (1859). Darwin posited natural selection as the mechanism whereby species-specific morphogenesis and behavior would need to show environmental adaptation (i.e., functionality) with regard to subsistence and reproduction. In simple terms, as long the new structure or behavior did not impair the animal's relative ability to compete for basic resources, it would continue to exist. Influenced by Darwin's work, William James (1890) similarly implied the existence of autoshaping in discussions of instinct. According to James, an instinct was defined as "the faculty of acting in a such a way as to produce certain ends, without foresight of the ends, and without previous education in the performance" (p. 383). But instincts were not to be considered immutable stimulus-response relations; they were to be considered "blind" to the resultant consequences of the action on the first occurrence of the behavior, after which they could be "disguised" or "modified." Hence, fixed action patterns, an interchangeable term for instinct used by ethologists, may be more or less fixed depending upon the effect of the behavior as well as the species under consideration. James implicated the existence of a process whereby innate, hard-wired behavior might interact with and be modified by resultant environmental stimuli.

Lorenz (1957), an early ethologist, posited the more widely held view that due to the simplicity of the nervous system of lower animals, constraints on stimulus perception and response are more likely than in humans and that those responses would be adaptive to the survival of the animal. This view on instinct proposed a mechanism whereby the animal perceived a stimulus that *released* a species-specific response (e.g., pecking) designed to provide a specific consequence (e.g., food). This paradigm also adhered to the assumption that instinctive responses were unlearned, yet were modifiable, although the modification would only be found in the offspring. Lorenz postulated that the fixed action pattern released by a specific stimulus should be referred to as an instinct; all supporting, orienting, or learned behaviors maintaining or modifying an instinct are to be considered appetitive responses. But, in practice, the line between instinctive and appetitive behaviors remained blurred, perhaps because the etiology of instincts or phylogenically predisposed fixed action patterns was not well understood.

Better understood are ontogenic models for acquiring behavior within the life of the animal. Two specific forms of learning, classical and operant conditioning, appear relevant to autoshaping. In the aforementioned example with autoshaped pecking in pigeons, it was originally thought that innate aspects of the bird provided for, or predisposed the bird for, rapid shaping via reinforcement of successive approximations of pecking. However, introducing terms like *innate aspect* or *predisposition* weakened the scientific explanation, as those terms were not operationally defined, did little to advance the understanding of the data, and were usually tautological (i.e., based on circular reasoning). Brown and Jenkins (1968) were the first to report that noncontingent food presentation temporally contiguous with key illumination resulted in pigeon pecking. Furthermore,

Williams and Williams (1969) conducted the first example of omission training with pigeons, whereby the presentation of food was contingent upon the nonoccurrence of pecking. Under an omission training model, behavior under operant control would cease or become greatly reduced. However, the pigeons continued to exhibit pecking over many trials without food. This study underscored the implausibility that autoshaping was maintained by contingent reinforcement with food, even if intermittently or superstitiously. This prompted researchers to investigate the possibility that key pecking was classically conditioned.

The rationale for considering classical conditioning as the mechanism of action for autoshaping stems from the fact that within each operant there resides the potential for simultaneous classical conditioning (for in-depth discussion, refer to texts by Davis & Hurwitz, 1977; Honig & Staddon, 1977; Rachlin, 1976; Schwartz, 1989). Due to the stimulus properties of consequences, particularly primary consequences, neutral stimuli that reliably precede and predict delivery may become conditioned. In other words, reinforcers and punishers may also serve as unconditioned stimuli–unconditioned response (US-UR) pairs, inadvertently creating conditioned stimuli (CS) and conditioned responses (CR). In the example with pigeons, the food pellet was contingently delivered upon pecking at the key when illuminated. This food pellet, both a potential reinforcer and paired US-UR, might allow the light inside the key to become a CS that elicits a key-pecking response (CR) that closely approximates a normal unconditioned eating response (UR). This model fits the data well, as autoshaped behaviors closely approximate the normal phylogenic response released by the goal stimulus. In a further testing of this model, noncontingent delivery of the food maintained key pecking as long as the illumination preceded and was temporally contiguous to the food delivery, that is, CS continued to evoke the CR when it reliably predicted the US-UR delivery (Brown & Jenkins, 1968). Later, Jenkins (1977) altered the predictability of the CS so that it no longer preceded the food delivery. Classical conditioning extinction curves were noted, as were spontaneous remission curves when contiguity was reestablished. Jenkins also noted that maintenance of the pecking response was best when both contiguity and contingency were in place (i.e., classical and operant conditioning may be additive processes).

In summary, autoshaping appears to be primarily a function of classical conditioning in that underlying US-UR relations are a requisite condition. However, operant consequences may also serve as US-UR pairs, allowing the occurrence of classical conditioning. Autoshaping per se only manifests when operant training appears to be overriding US-UR patterns, or in the terms of James and Lorenz, attempting to modify instinctive fixed action patterns for obtaining goals. Hence, behaviors exhibited during autoshaping continue to defy simple categorization and precise etiologic explanation.

AVOIDANCE LEARNING

Avoidance learning occurs when an individual's behavior prevents exposure to an unpleasant consequence. This arrangement, or contingency, is pervasive in everyday life. For example, in writing a mortgage check each month, the homeowner does so not because this behavior is immediately pleasurable but, rather, it avoids conflict with, and possible foreclosure by, a financial lender. Or, consider the motorist who is traveling above the speed limit posted on a highway. Upon seeing the blinking light of a police vehicle ahead, the driver slows down to avoid a negative encounter with law enforcement. It might be said, in fact, that learning by avoidance is what motivates most people most of the time.

Avoidance learning has its roots in experimental psy-

chology and conditioning theory. This chapter describes its theoretical basis, reviews conceptual issues, and discusses the role of avoidance learning in clinical psychology.

Theory

B. F. Skinner was a psychologist who, among other things, studied the effects of behavior consequences on animal and human learning. Although he wrote extensively about many topics, he is most commonly associated with the principles of positive and negative reinforcement. Positive reinforcement is the presentation of a pleasurable consequence following a behavior, with the result being an increase in the future probability of that behavior. By contrast, negative reinforcement is the behavior-contingent *removal* or *postponement* of a nonpleasurable experience, which also produces an increase in responding.

As noted, negative reinforcement can operate in two ways. When one's behavior stops or reduces ongoing contact with an unpleasant experience, it functions as "escape." To illustrate, turning up the thermostat at home during winter months will terminate the cold temperature in a room. With the second operation, the individual is not confronted with a contemporaneous unpleasant situation but behaves to prevent or avoid its occurrence. Escape responding, therefore, requires that the behavior be demonstrated in the presence of the nonpreferred (negative) situation, whereas avoidance responding occurs in the absence of the nonpreferred (negative) situation.

Avoidance learning can be traced to the study of *discriminated avoidance* that emerged from animal research. A neutral stimulus, such as a light or tone, was presented to a rat in an experimental chamber preceding the delivery of electric shock through a grid floor. If the rat pressed a lever during a preset interval between onset of the stimulus and the noxious stimulation, the electric shock would be prevented. The behavior of lever pressing is "discriminated" because it does not occur in the absence of the light or tone, which have become a warning signal.

Other Considerations in Avoidance Learning

As revealed in the preceding example with lower organisms, avoidance learning is predicated on exposure to aversive stimulation that subsequently can be predicted by an exteroceptive cue or signal. Among humans, however, similar learning can be promoted without direct contact with an unpleasant situation. On one hand, an individual's behavior may adhere to the avoidance paradigm by *observing* the performance of other people. Avoiding interpersonal difficulties with a supervisor on the job, for instance, might be the outcome for a worker who sees colleagues chastised or rebuked, or receive similar harsh consequences, when they interact with that individual.

Learning through avoidance without actually experiencing negative situations also can be the result of giving an individual verbal instructions, directions, or explanations. Such is the case when a parent informs a young child, "Don't touch the stove," in order to prevent injury. Similarly, the visibility of "Do" and "Don't" signs abundant in our environment provides explicit warnings for the purpose of avoiding untoward (and possibly fatal) consequences. Verbal and written language is said to mediate or control behavior through rule governance.

Avoidance Learning in Clinical Psychology

Within clinical psychology, avoidance learning is pertinent in both understanding the causes of maladaptive behaviors and formulating methods to intervene therapeutically. Relative to etiology, psychologists have long posited that experiential avoidance is at the heart of many clinical disorders. Thus, a person who struggles to cope effectively may abuse alcohol or use illicit drugs to avoid confronting sources of stress and discomfort.

When implemented for therapeutic purposes, avoidance learning is promoted according to a five-step process: (1) identifying a problem behavior to be reduced or eliminated, (2) selecting a response to serve as replacement for the problem behavior, (3) choosing a negative consequence, (4) pairing the negative consequence with the problem behavior, and (5) allowing the person receiving treatment to avoid the negative consequence. Although this step-wise progression looks like a straightforward process, it is not without complications. First, there are ethical concerns when proposing or using negative and distressing events with individuals who already have adjustment difficulties. Second, even if an avoidance learning approach to treatment seems appropriate, it can be an arduous task arranging contiguous behavior and unpleasant conditions. And third, negative reinforcement generally would not be considered the sole basis of treatment, but instead it would be combined with other therapeutic procedures to prompt and maintain compensatory skills.

Avoidance learning for therapeutic purposes is employed typically by professionals from the disciplines of behavior therapy and behavior modification. Beginning in the early 1960s, several research reports by behavioral psychologists described examples of avoidance conditioning that incorporated extremely aversive stimulation. In one demonstration, children who had autism and were unresponsive to social interaction learned to avoid electric shock by approaching a therapist who called to them, "Come here." Faradic and other noxious stimuli such as foul odors and tastes also were programmed with individuals to condition avoidance of cues and situations associated with alcohol ingestion, drug use, and "deviant" sexual orientation. By contemporary standards these approaches would be unacceptable and viewed by some as dehumanizing. In fact, the majority of behavioral practitioners have essentially abandoned aversive treatment procedures in favor of positively oriented and skill-building strategies.

Although avoidance learning is still included in many current therapies, the types of negative experiences are more benign than those found in the historical record. As a whole, and when contrasted to other behavior-change procedures, avoidance learning and training is used less frequently in clinical practice. Again, because avoidance must be produced by exposure (real or threatened) to unpleasant conditions, it should be considered cautiously and applied with great care on those occasions when it can be justified clinically.

Summary

Avoidance learning is a powerful influence on human behavior. It is generated by encountering a negative situation, observing other people in similar circumstances, or being informed about the consequences of behavior. Verbal and written language serve frequently as warning stimuli that occasion avoidance-maintained responding. In a clinical context, avoidance learning has been incorporated to overcome problems and teach compensatory skills.

AVOIDANT PERSONALITY

Avoidant personality, or Avoidant Personality Disorder (APD), is a label included in the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association to describe a condition in which a person

1. Avoids occupational activities that involve significant interpersonal contact because of fears of criticism, disapproval, or rejection
2. Is unwilling to get involved with people unless certain of being liked
3. Shows restraint within intimate relationships because of the fear of being shamed or ridiculed
4. Is preoccupied with being criticized or rejected in social situations
5. Is inhibited in new interpersonal situations because of feelings of inadequacy
6. Views self as socially inept, personally unappealing, or inferior to others
7. Is unusually reluctant to take personal risks or to engage in any new activities because of potential embarrassment (*DSM-IV,* 1994, pp. 664–665)

Avoidant Personality Disorder is found in approximately 1% of the general population and in 10% of individuals seeking outpatient treatment from mental health clinics. This personality pattern occurs equally in men and women. Although APD can begin when people are in their teens, many avoidant individuals report that they have been socially anxious for as long as they can remember. Individuals with APD commonly display a variety of other clinical disorders, in particular, the anxiety disorders, mood disorders, and schizophrenic-spectrum disorders. Empirical studies also indicate that between 15% and 30% of people who abuse alcohol meet the criteria for APD, which suggests that long-standing social avoidance may increase vulnerability to substance dependence.

Personality types characterized by social sensitivity and withdrawal appear in earlier clinical descriptions of personality disorders; however, contemporary views of avoidant personality disorder have their origins in Theodore Millon's biosocial learning theory. In his book *Disorders of Personality* (1981), Millon proposed that the avoidant pattern develops when a child with a fearful or anxious temperament is exposed to early social experiences characterized by persistent deprecation, rejection, and humiliation. Avoidant individuals learn what Millon labeled an *active-detached* coping pattern. This consists of behavioral strategies designed to protect the person from the painful emotions he or she expects to result from interpersonal encounters.

Cognitive and interpersonal models of APD have also been developed. In their book *Cognitive Therapy of Personality Disorders* (1990), Aaron Beck and Arthur Freeman emphasized the role of cognitive schemas that develop in response to traumatic early social experiences and/or biological sensitivities. According to these writers, schemas—the cognitive structures that organize experience—include beliefs and rules of conduct, which for the avoidant person take such forms as "If people get close to me they will reject me" and "Don't stick your neck out." Although accurate in an historical sense, these schemas are hypothesized to lead to distortions in processing current social information and to the adoption of maladaptive interpersonal strategies.

Interpersonal writers emphasize the contribution of self-perpetuating transactional cycles to the onset and maintenance of APD. According to these writers, early social experiences lead avoidant individuals to develop beliefs about people that color their interpretations of current interactions. As a result, they adopt behaviors that provoke negative reactions from others, thereby confirming their original beliefs. In short, people with APD are caught in a cycle of unwittingly reenacting the early significant relationships that led to the development of their underlying fears. Consistent with all of these theories, research indicates that childhood maltreatment, particularly neglect, increases the likelihood that a person will develop APD.

There are similarities between APD and personality traits such as shyness and behavioral inhibition. The primary distinction is that APD is characterized by greater distress and impairment. Shyness and behavioral inhibition have been shown to arise in part from innate differ-

ences in physiological reactivity to environmental change. This suggests that individuals with APD either have stronger biological dispositions toward anxiety than do shy people or have experienced more negative social developmental events that exacerbate innate biological vulnerabilities.

Avoidant Personality Disorder also shares features with several other clinical conditions, most notably generalized Social Phobia (GSP) and Dependent Personality Disorder (DPD). A substantial number of individuals with APD also meet diagnostic criteria for GSP, and as many as 60% of patients with GSP meet criteria for APD. Comparative studies indicate that patients with APD report greater social anxiety and depression and lower self-esteem, and they display more comorbid diagnoses than do patients with GSP alone, but few other differences emerge. Avoidant Personality Disorder also overlaps with DPD. Research suggests that only the symptom of social withdrawal reliably discriminates the two conditions, and in practice, diagnoses of APD and DPD often co-occur. Distinctions between APD, GSP, and DPD require further study.

A variety of treatment strategies for APD have been evaluated, including cognitive-behavioral, interpersonal, and pharmacological regimens. Empirical studies show that behavioral and cognitive-behavioral treatment programs produce significant improvement in social comfort and activity in avoidant individuals and may be more effective than psychodynamic therapies. Overall, psychological treatments produce significant gains in avoidant patients, and these gains are maintained, at least over the year following treatment termination. On a less positive note, many APD individuals remain at the low end or below normative levels of social functioning even after treatment. This suggests that avoidant individuals may require a longer course of treatment or that biological factors or early trauma limit change. Pharmacological regimens have also been examined, primarily in the context of treating patients with Social Phobia. The monoamine oxidase inhibitors (MAOIs), particularly phenelzine, and the serotonin-reuptake inhibitors (SRIs) are considered the most effective pharmacological interventions presently available. Even patients who respond to medication, however, can continue to have some problems with social avoidance, and further work on the treatment of this long-standing condition is required.

B

BABINSKI SIGN

In 1896, Joseph François Félix Babinski (1857–1932) reported the clinical sign that now bears his name. Babinski noted that stimulation of the soles of the feet of some patients with unilateral paralysis induced, not the expected flexion, but rather the extension of the great toe on the paralyzed side (Babinski, 1896). Others had seen this reflex response, but Babinski was the first to recognize and call attention to its diagnostic importance, for example, in differentiating structural from hysterical paralysis (Babinski, 1898). He later pointed out that fanning of the lateral toes may accompany extension of the great toe (Babinski, 1903).

The sign is best elicited by having the patient lie supine with the leg uncovered and supported by the examiner. After informing the patient about what is to happen, a stimulus (ranging from light touch to moderately firm and slightly noxious pressure from a blunt object like a wooden applicator stick or key) is applied to the lateral plantar surface of the foot in a gentle, sweeping motion from heel to ball (van Gijn, 1995). The hallmark positive (extensor) response is mediated by contraction of the long extensor of the great toe (*extensor hallucis longus*). Careful observation for tightening of the *extensor hallucis longus* tendon may resolve doubts about whether the sign is present. Extensor responses can be evoked by stimuli applied to a number of other loci on the foot or leg, but the interpretation of the response is the same. Extension of the toe (away from the noxious stimulus on the sole) is part of a generalized flexion response of the stimulated limb, so visible flexion of thigh on hip, leg on knee, and foot on ankle may occur, brought about by contraction of the tibialis anterior, hamstrings, tensor fasciae latae, and iliopsoas muscles, respectively (Bassetti, 1995).

The clinical significance of the Babinski sign is found by reviewing its developmental course. A positive response has been reported in 10–90% of normal newborns (Hogan & Milligan, 1971; Jaynes, Gingold, Hupp, Mullett, & Bodensteiner, 1997). The pyramidal tracts of the central nervous system, carrying neurons from the motor cortex into the spinal cord, subserve voluntary muscle function throughout the body. As these tracts mature during the first 6 months of life, the toe response changes from extensor to flexor by the age of 9–12 months (Katiyar, Sen, & Agarwal, 1976); the entire flexion response of the lower extremity is extinguished along with the Babinski response (van Gijn, 1995).

Since maturation of the pyramidal tracts underlies the developmental disappearance of the Babinski response, it is not surprising that persistence of the response after the first year of life—or its later reappearance, especially if laterally asymmetrical—indicates disease affecting the pyramidal tract. As Babinski knew, the sign often accompanies destructive lesions of the motor fibers innervating the foot; in these patients careful testing may reveal weakness of the affected limb or at least disturbances of fine motor function (Bassetti, 1995).

Now, more than 100 years after its initial description, the extensor response of the great toe remains one of the best known and clinically useful of the eponymic signs in clinical medicine. Its unilateral presence almost always indicates serious structural abnormalities of the upper motor neurons serving the affected limb. The finding of a positive Babinski response after the first year of life should be considered abnormal and appropriate neurological investigation should be undertaken to identify the nature and location of the abnormal process.

THE BECK DEPRESSION INVENTORY-II

The Beck Depression Inventory-II (BDI-II; Beck, Steer, & Brown, 1996) is a 21-item self-report instrument for measuring the severity of depression in adolescents and adults according to symptoms corresponding to the criteria for diagnosing major depressive disorders listed in the fourth edition of the American Psychiatric Association's (1994) *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*). It is the upgraded version of the amended Beck Depression Inventory (BDI-IA; Beck & Steer, 1993), which, in turn, replaced the original instrument developed by Beck, Ward, Mendelson, Mock, and Erbaugh (1961).

The BDI-II is scored by summing the highest rating for each of the 21 symptoms, and a 4-point scale ranging from 0 to 3 is employed for each item. Respondents are asked to rate each symptom for the past 2 weeks, through that day. This instrument generally requires between 5 and 10 minutes to complete. Beck, Steer, and Brown (1996) suggested the following cutoff score guidelines for evaluating the severity of self-reported depression in patients diagnosed with major depressive disorders: Total scores from 0 to 13 are "minimal," and those from 14 to 19 are "mild." Scores from 20 to 28 are "moderate," and scores from 29 to 63 are "severe."

Reliability

The internal consistency of the BDI-II has repeatedly been described as high with a coefficient alpha of approximately .90 in adolescent (Steer, Kumar, Ranieri, & Beck, 1998) and adult psychiatric patients (Steer, Ball, Ranieri, & Beck, 1997) and college students (Dozois, Dobson, & Ahnberg, 1998; Osman, Downs, Barrios, Kopper, Gutierrez, & Chiros, 1997; Steer & Clark, 1997). Beck, Steer, and Brown (1996) reported that the 1-week test-retest reliability was also high ($r = .93$) for 26 outpatients who completed the BDI-II before their first and second cognitive therapy sessions.

Validity

For their normative samples of 500 outpatients who were diagnosed with various psychiatric disorders and 120 college students, Beck, Steer, and Brown (1996) described a number of analyses that supported the convergent and discriminant validities of the BDI-II. For example, the BDI-II was more positively correlated with the revised Hamilton Psychiatric Rating Scale for Depression (Riskind, Beck, Brown, & Steer, 1987; $r = .71$) than it was with the revised Hamilton Rating Scale for Anxiety (Riskind et al., 1987; $r = .47$) in 87 outpatients.

Factor Structure

Beck, Steer, and Brown (1996) found that the BDI-II was composed of two positively correlated *cognitive* and *noncognitive* (*somatic-affective*) dimensions for both psychiatric outpatients and students. The noncognitive factor is represented by somatic symptoms, such as loss of energy, and affective symptoms, such as irritability, whereas the cognitive factor is composed of psychological symptoms, such as self-dislike and worthlessness. Steer, Ball, Ranieri, and Beck (1999) also identified these two factors in 210 adult outpatients (age 18 or older) who were diagnosed with *DSM-IV* depressive disorders, as did Steer, Kumar, Ranieri, and Beck (1998) in 210 adolescent psychiatric outpatients and Steer, Rissmiller, and Beck (2000) in 130 depressed geriatric inpatients (age 55 or older). These two dimensions were also reported by Steer and Clark (1997) and Dozois, Dobson, and Ahnberg (1998) for college students and by Arnau, Meagher, Norris, and Bramson (2001) for primary-care medical patients. However, Osman and colleagues (1997) found three factors representing *negative attitudes, performance difficulty,* and *somatic elements* in 230 college students, and Buckley, Parker, and Heggie (2001) also found three factors representing *cognitive, affective,* and *somatic* dimensions in 416 male substance abusers.

BEHAVIOR GENETICS

The past two decades have produced an exponential increase in research examining the genetic and environmental factors that influence both normal and atypical patterns of behavior. This rapid accumulation of new knowledge illustrates the broad impact of behavioral and molecular genetic methods. However, the results of these studies have also underscored the complexity of the etiological pathways for all psychological traits and demonstrate clearly how much is yet to be learned.

The first section of this entry provides a brief overview of behavioral genetic methods that can be used to determine the extent to which a psychological trait or disorder is due to genetic or environmental influences. The second section describes molecular genetic techniques that can then be applied to localize genes that increase risk for the disorder. Finally, the concluding section summarizes several key implications and future directions of behavioral genetic studies.

Behavioral Genetic Methods

Behavioral genetic methods are designed to estimate the relative influence of genetic and environmental factors on individual differences in a trait or in symptoms of a disorder. The influence of genes is quantified by estimating *heritability,* the proportion of the population variance in a trait that is attributable to genetic influences. The proportion of variance due to environmental factors can be subdivided into *shared* and *nonshared environmental influences.* Shared environmental influences are those that similarly influence members of a family, thereby increasing the similarity of individuals within a family in comparison to unrelated individuals in the population. In contrast, nonshared environmental influences either affect just one individual in a family or have a different effect on different family members. In either case, nonshared environmental influences are those that lead to differences among individuals in a family.

Family Studies

Because individuals cannot be randomly assigned to different environmental or genetic backgrounds, family, adoption, and twin studies take advantage of different naturally occurring events to estimate the extent to which a trait or disorder is due to genetic or environmental influences. In the family study design the rate of a disorder is compared among the biological relatives of individuals with and without the disorder. If the disorder occurs more often in the family members of individuals with the disorder, this suggests that familial factors increase risk for the disorder.

Previous family studies have found that most psychological traits and disorders are significantly familial. However, because a disorder could run in families because of either genetic influences or shared environmental factors, adoption and twin studies are necessary to disentangle their relative contributions.

Adoption Studies

The adoption study design compares the prevalence of a disorder among adoptive and biological relatives of individuals with the disorder. The biological relatives of an individual who has been adopted are related genetically to the individual but have not shared any environmental influences. In contrast, adoptive relatives live in the same family environment but are biologically unrelated to the individual. Therefore, if a disorder is due to genetic factors, the biological relatives of individuals with the disorder should exhibit a higher rate of the disorder than the population base rate, whereas an elevated rate of the disorder among adoptive relatives would suggest that family environmental influences play a role in the etiology of the disorder.

The adoption design is quite elegant and has been helpful for some disorders, but two specific constraints have limited the utility of adoption studies. Most importantly, in societies in which adoption records are closed, it is often quite difficult to obtain information from the biological relatives of individuals who are adopted. Moreover, adoptive parents may not be representative of the overall population of parents due to the laudable desire of adoption agencies to place

adopted children in an optimal environment with high-functioning parents with many available resources.

Twin Studies

By comparing the similarity of monozygotic (identical) twins, who share all of their genes, to dizygotic (fraternal) twins, who share half of their segregating genes on average, the twin-study methodology facilitates the estimation of the proportion of the total variance in a trait that is attributable to the influence of genes, shared environment, and nonshared environment. Results of large population-based twin studies have shown that genetic influences are significant for virtually all psychological traits and disorders. Similarly, environmental factors also play an important role in the etiology of nearly every trait or disorder that has been studied, although nonshared environmental influences are often slightly stronger. Therefore, the question is no longer whether a trait is due to nature *or* nurture, but instead the extent to which each of these factors and the interactions between them influence the development of the trait. In the next section we turn to methods that can be used to identify the specific genes that influence these behaviors.

Molecular Genetic Approaches

Although an estimated 99.8% of the deoxyribonucleic acid (DNA) sequence that comprises the human genetic code is identical among all people, the genetic sequence varies at thousands of locations across the remaining 0.2% of the human genome. Many of these sequence differences cause individual differences in protein production, which may then lead to individual differences in neural development or adult brain functioning if the sequence differences occur in a gene that are expressed in the central nervous system. Two primary methods can be used to identify the approximate location of genes that contain sequence differences that influence a trait.

Candidate Genes

The candidate gene approach is useful if previous research has identified specific biological substrates that are associated with the disorder. For example, if a disorder is known to be associated with elevated or depleted levels of a specific neurotransmitter, plausible candidate genes can be identified that influence some aspect of this neurotransmitter system. Candidate gene studies have identified several intriguing associations between genes in the dopamine and serotonin systems and psychological traits and disorders such as novelty seeking, neuroticism, Attention-Deficit/Hyperactivity Disorder, Schizophrenia, and Bipolar Disorder. However, subsequent studies often fail to replicate the initial results, suggesting that these genes may have relatively small effects.

Linkage and Association

Although the candidate gene approach is useful when viable candidates can be identified based on previous research, the etiology of many disorders is not understood sufficiently well to identify likely candidate genes. In the absence of an a priori reason to examine specific candidate genes, family-based linkage analysis can be used to screen broad sections of the genome to identify regions that may contain a gene that increases susceptibility to a disorder, and association analyses can be used to narrow further the region that contains a gene that influences the trait or disorder. Linkage and association analysis take advantage of the fact that genes that are close together on a chromosome tend to be transmitted together across many generations. Although these methods typically do not identify a gene with functional significance for the disorder of interest, they facilitate the identification of smaller regions of the genome that may be fruitful targets for further focused studies.

Determining Gene Function

After a gene that influences behavior has been identified, the function of the gene must be determined. This can be accomplished by first mapping the entire sequence of the gene to identify specific sequences that vary among people. These sequence differences are then used to determine the specific proteins that are produced by the gene, and a variety of techniques can be applied in studies of humans or animals to determine the function of the gene.

The Future of Behavior Genetic Research

Implications for Psychiatric Diagnoses and Diagnostic Systems

In contrast to conditions such as Parkinson's Disease that are caused by a single gene, increasingly, data suggest that virtually all psychological traits and disorders are caused by a combination of many genetic and environmental risk factors. Moreover, it is likely that many of these genes increase risk for more than one disorder, suggesting that the boundaries between putatively distinct diagnoses may prove to be blurry. Behavioral and molecular genetic methods will provide an essential tool to improve the nosology of psychiatric diagnoses by revealing the common and unique risk factors that contribute to the development of complex disorders.

Prevention and Treatment

Results of future behavioral and molecular genetic studies are likely to facilitate the development and application of effective primary prevention and early intervention techniques that would be impossible without understanding of

the etiology of the disorder. For example, if a screening revealed that an infant had significant genetic susceptibility to reading difficulties, tutoring could be implemented to improve important reading-related language processes before the child even began to learn to read. Similarly, knowledge about the specific genetic or environmental etiology of a disorder will enable tertiary treatments that target directly these causal factors.

Accessibility

In closing, it is worth noting that procedures for DNA collection and genetic analysis continue to become more automated and efficient. It is rapidly becoming possible for researchers with even relatively modest budgets to include a behavior genetic component within their study. The ability to apply these methods to a broad new set of psychological questions will facilitate an extraordinary kind of collaborative synergy between behavior genetic researchers and investigators in other areas of psychology and psychiatry that can only serve to strengthen the studies in both domains.

BEHAVIOR MODIFICATION

Behavior modification is the field of study that focuses on using principles of learning and cognition to understand and change people's behavior (Sarafino, 1996). Although not all experts in this field would include cognitive processes in the definition (see Lee, 1992; Sweet & Loizeaux, 1991; Wolpe, 1993), these processes have been widely adopted and applied by behavior modification professionals since the early 1970s (Dobson, 1988; Kazdin, 1978; Mahoney, 1993; Williams, Watts, MacLeod, & Mathews, 1988).

Defining Characteristics of Behavior Modification

The field of behavior modification has several characteristics that make its approach unique (Kazdin, 1978; Wixted, Bellack, & Hersen, 1990). First, professionals in this field focus on people's *behavior,* which can be *overt,* such as motor or verbal acts, or *covert,* such as feelings, thoughts, or physiological changes. As a result, their approach typically involves (1) defining people's current status and progress in terms of behavior rather than traits or other broad features, (2) measuring the behavior in some way, and (3) whenever possible, assessing covert behaviors, such as fear, in terms of overt actions. Efforts to improve behavior can be directed at a *behavioral deficit*—that is, the behavior occurs with insufficient frequency, strength, or quality—or a *behavioral excess*—that is, it occurs too frequently or strongly. The behavior to be changed is called the *target behavior.*

Second, although behavior modification professionals recognize that injury and heredity can limit the abilities of an individual, they assume that human behavior is, for the most part, *learned* and influenced by the environment. The most basic types of learning are *respondent (classical) conditioning*—in which a stimulus gains the ability to elicit a particular response by being paired with an unconditioned stimulus that already elicits that response—and *operant conditioning*—in which behavior is changed by its consequences. The methods applied in behavior modification generally involve altering the *antecedents* and *consequences* of the target behavior.

Third, behavior modification has a strong scientific orientation. As a result, there is a major focus on carefully gathering empirical data, analyzing and interpreting the data, and specifying the precise methods used to gather and analyze the data. The field is also quite pragmatic, emphasizing the need to find and use techniques that work, as indicated by carefully conducted research. Fourth, behavior modification techniques for changing behavior often have clients or subjects become active participants, such as by performing "homework" and "self-management" activities, in the process of modifying their behavior.

History of Behavior Modification

Behavior modification developed from the perspective called *behaviorism,* which emerged with the work of John B. Watson (1913, 1930) and B. F. Skinner (1938, 1953). This perspective emphasizes the study of observable and measurable behavior and proposes that nearly all behavior is the product of learning, particularly operant and respondent conditioning. Three lines of research laid the foundation for behaviorism. Ivan Pavlov (1927) demonstrated the process of respondent conditioning. John Watson and Rosalie Rayner (1920) showed that an infant, "Little Albert," learned to fear a white rat through respondent conditioning. And Edward Thorndike (1898, 1931) studied how "satisfying" and "annoying" consequences—which we now call *reinforcement* and *punishment*—affect learning. Other studies formed the basis for applying the ideas of behaviorism by showing that conditioning techniques could effectively reduce fears (Jones, 1924) and improve problem behaviors of psychiatric patients (Ayllon & Michael, 1959; Lindsley, 1956). The field of behavior modification now includes the areas of the *experimental analysis of behavior,* which examines basic theoretical processes in learning, *applied behavior analysis,* which emphasizes application to socially important problems in various settings, and *behavior therapy,* which focuses on application in psychotherapy settings.

Application and Techniques of Behavior Modification

Behavior modification techniques have been applied successfully in a wide variety of settings and with many types of behaviors and populations (Sarafino, 1996). They have been used to improve general parenting skills, help parents correct children's problem behaviors, enhance instructional methods in schools, improve classroom conduct, train developmentally disabled children in self-help skills, reduce substance abuse, reduce depression and anxiety, promote people's health and prevent illness, and improve worker productivity and safety.

The techniques used in modifying behavior are quite varied. Operant techniques include some that deal with the consequences of behavior. In *reinforcement,* consequences strengthen the target behavior. *Positive reinforcement* involves introducing a pleasant event after the target behavior, and *negative reinforcement* involves removing or reducing an aversive circumstance if the target behavior occurs. *Extinction* is a procedure whereby eliminating the reinforcers of a target behavior weakens that behavior. When *punishment* is used as a consequence, it suppresses the target behavior. Operant techniques also address the antecedents of the target behavior. For instance, *prompting* involves using a stimulus to remind individuals to perform a behavior they know how to do or help them perform a behavior they do not do well. Other operant methods concentrate on the behavior itself. *Shaping* improves a target behavior by requiring better and better performance to receive reinforcement, and *chaining* is used to develop complex motor behaviors by organizing simple responses into a sequence.

Respondent techniques are usually applied to reduce conditioned emotional responses, such as fear or anger. One technique is *extinction,* in which a conditioned response is weakened by repeatedly presenting the conditioned stimulus without the unconditioned stimulus. Another method is *systematic desensitization,* whereby a conditioned emotional response is reduced by having the person experience increasingly strong conditioned stimuli while maintaining a relaxation response. The conditioned stimuli are arranged in a hierarchy from a very weak stimulus to a very intense one.

Other behavior modification techniques include *modeling,* a vicarious process in which individuals learn a behavior by watching someone else perform it; biofeedback; and various cognitive methods, such as relaxation training, thought stopping, and covert sensitization. *Biofeedback* is a technique that teaches people to regulate physiological functioning by presenting moment-by-moment information about the status of the body system. The form of relaxation that is most commonly applied in behavior modification is *progressive muscle relaxation,* which has the person alternately tense and relax separate muscle groups. Once the relaxation response is mastered, the procedure can be used by itself or as part of systematic desensitization. *Thought stopping* is a technique in which individuals interrupt distressing thoughts by saying "Stop" emphatically, either aloud or covertly. *Covert sensitization* is a method that is used to teach a person to dislike a liked event, such as drinking alcohol, by pairing it repeatedly with an aversive event in an imagined situation.

Applying behavior modification is a creative enterprise that organizes techniques into programs that are tailored to meet the needs of specific clients in particular circumstances.

BEHAVIOR THERAPY: PROBLEMS AND ISSUES

Behavior therapy is an increasingly accepted part of the mental health establishment, bringing with it an influx of professional issues pertaining to clinical strategies, training, licensing, guidelines, accountability, legal constraints, and a host of problems encountered in the hurly-burly of daily practice.

Behavioral procedures go back to antiquity. What is new is the systematic application and formulation of the principles in terms of scientific methodology. This methodology contains within it the following features: objectivity, quantification, replicability, validation, hypothesis testing, reliance on data and reason rather than appeal to authority, and an obligation to submit feasible alternative explanations to scientific scrutiny.

For some behavior therapists, the conceptual framework is Pavlovian classical conditioning translated into practice by such techniques as aversion therapy and systematic desensitization. For other behavior therapists, the primary influence is Skinnerian operant conditioning and an empirical analysis of behavior, leading to behavioral shaping, token economies, and so forth. For yet others, the uniqueness of behavior therapy lies in its emphasis on the application of experimental methodology to individual cases. For social learning theorists, modeling and conditioning principles have been incorporated into a performance-based schema with the individual and the environment exerting reciprocal and interactive influences.

Some behavior therapists accept trait theories; others do not. For some, the environment is all-encompassing; for others, physiological and constitutional factors are paramount. Some view behavior therapy as in large part an exercise in self-actualization, but for others, self-control is a delusion. For this latter group, there is no such thing as a self; the guiding principle is radical or metaphysical behaviorism, with a complete denial of any intervening variable between stimulus and response. For some behavior therapists, data are sufficient and theory is of little or no consequence; for others, theory is essential if behavior therapy is to advance.

Most behavior therapists share certain characteristics in addition to or arising out of methodology. These include a focus on current rather than historical determinants of behavior, an emphasis on overt behavior change as a main criterion by which treatment is to be evaluated, the delineation of treatment in objective terms to make replication possible, a reliance on basic research as a source of hypotheses about treatment and specific techniques of intervention, and a specificity in defining, treating, and measuring target populations.

The definition of behavior therapy tentatively adopted by the Association for Advancement of Behavior Therapy in the early 1970s was as follows:

> Behavior therapy involves primarily the application of principles derived from research in experimental and social psychology for the alleviation of human suffering and the enhancement of human functioning. Behavior therapy involves a systematic evaluation of the effectiveness of these applications. Behavior therapy involves environmental change and social interaction rather than the direct alteration of bodily processes by biological procedures. The aim is primarily educational. The techniques facilitate improved self-control. In the conduct of behavior therapy, a contractual agreement is negotiated, in which mutually agreeable goals and procedures are specified. Responsible practitioners using behavior therapy are guided by generally accepted principles.

Behavior therapy started in the 1950s. Its first decade was characterized by ideology and polemics, the second by consolidation, and the third by the development of sophisticated methodology, innovative conceptual models, and a search for new horizons. These developments involve an increasing acceptance of inner processes (the so-called cognitive revolution), a growing interdisciplinary basis, and a broadening interface with the community. Because of this expanded domain, and because behavior therapy is not a unitary system with circumscribed therapeutic procedures, conceptual problems and issues arise.

Stimulus-Response Learning Theory and Conditioning in Behavior Therapy

There is increasing evidence that behavior therapy is firmly based on neither theories nor principles of conditioning. Conditioning is devoid of precise meaning. The differentiation between classical and operant conditioning remains equivocal. The relationships between conditioning in the laboratory, conditioning in the clinic, and conditioning in daily life are complex and open to diverse interpretations. No general factor of conditionability has as yet been demonstrated, even though it is an implicit assumption underlying much of behavior therapy. Neither classical conditioning, operant conditioning, nor applied behavioral analysis accounts adequately for the many complexities of neuroses. Attempts to update conditioning theory in terms of cognition, subjective experience, or interaction response patterns could complicate rather than clarify the issue.

Thus the evidence for conditioning as an explanatory concept in behavior therapy is, at best, equivocal.

Were it to be granted that behavior therapy is based on theories of learning, there is still little agreement about which learning theories or principles are applicable. Whether the prevailing concepts of conditioning are adequate to account for covert, inner-directed processes is yet unresolved. It is occasionally proposed that the foundation of behavior therapy be broadened to include knowledge drawn from social psychology, physiology, and sociology rather than relying exclusively on conditioning-based learning theory. To do so would be to change radically some of the premises on which behavior therapy is based.

A unifying factor in behavior therapy is generally considered to be its derivation from experimentally established procedures and principles that conform to the characteristic methodology of the behavioral scientist. Unfortunately, much of behavior therapy rests on limited scientific evidence. At best, behavior therapy is based on empirical validation rather than derivation from theory, and occasionally on little more than prevailing notions arising out of the clinical experience of the practitioner. Swan and MacDonald found that behavior therapy as actually conducted is not always consistent with the theories and principles espoused by the practitioners concerned.

Role of Cognition in Behavior Therapy

Perhaps because of a desire to discard anything that smacked of mentalism or inner processes, early behavior therapists resolutely rejected all forms of cognitive influence. Within two decades this situation changed drastically so that behavior therapy in the 1980s was in the throes of what was termed the "cognitive revolution." The emphasis on the role of cognition aroused considerable dispute and dialogue within the ranks of behavior therapy. For some behavior therapists, cognitions are not behaviors, but are hypothetical constructs used to account for relationships between the environment and behavior. For others, cognition is an integral part of behavior therapy, to be accounted for either in terms of some form of conditioning or by the introduction of an as yet undetermined additional explanatory concept.

The precise relationship between cognition and behavior remains equivocal. All therapies are probably simultaneously cognitive and behavioral to a greater or lesser extent. Further clarification must await the development of an appropriate technology of brain-behavior-cognitive function.

Virtually all current procedures in behavior therapy involve some cognitive influence. Most behavior therapists reject the radical or metaphysical approach in favor of some form of methodological behaviorism. It is more appropriate to regard contemporary behavior therapists as behavioral rather than behavioristic. Nevertheless, the debate about the behaviorism in behavior therapy is far from resolved, and the issue of what is and what is not philosophically legitimate remains a matter of lively controversy.

Certain individuals recognize the impossibility of philosophical or conceptual integration between psychoanalysis and behavior therapy but insist that some form of interaction is both feasible and desirable at the level of practice.

BEHAVIORAL INHIBITION

Behavioral inhibition is a consequence of an animal's capacity to learn both positive and negative relationships, whether these relationships involve stimuli or responses. The term arises from the seminal work of Pavlov (1927) in his studies of conditioned reflexes in hungry dogs. Pavlov found that an initially neutral conditioned stimulus (CS), such as the sound of a metronome, could acquire significance if it predicted the delivery of an unconditioned stimulus (US), such as meat powder. After a number of CS-US pairings, the CS would come to evoke a conditioned response (CR), such as salivation. This form of behavioral adaptation, known as excitatory conditioning, allowed the animal to prepare for the arrival of the US. Inhibitory conditioning is the counterpart of excitatory conditioning. Pavlov found that an initially neutral CS would acquire the ability to suppress the salivary CR (behavioral inhibition) if the CS signaled the absence of an expected US.

In *Conditioned Reflexes* (1927), Pavlov listed four experimental conditions under which responding is inhibited: (1) suppression of the CR evoked by an excitatory CS in the presence of a second "inhibitory" CS, (2) the gradual loss of the CR in extinction, (3) decreased generalized responding to an unreinforced CS when trained concurrently with a reinforced CS (called *differential conditioning*), and (4) diminution of the CR in the early portion of a long-duration CS. The first procedure is now the paradigmatic instance of what is called inhibitory conditioning.

Although Pavlov emphasized the importance of inhibitory conditioning, the idea was not initially well received. Interest in inhibitory conditioning was reawakened with the incorporation of inhibitory conditioning into correlative accounts of conditioning (e.g., Rescorla, 1967). During this time, the concept of inhibition also proved to be a powerful vehicle for understanding a wide range of clinically relevant behavioral phenomena. Of special interest was the persistence of phobic avoidance in the absence of further traumatic events. But the key development was Rescorla's (1969) introduction of the summation and retar-

dation tests. These special tests could be applied to detect the presence of inhibition independently of the conditions under which it was observed.

Since its first introduction, the idea that a CS may possess inhibitory properties has stirred a great deal of controversy. How can a CS be declared inhibitory merely on the basis of a reduction in the probability of the CR? To resolve such a controversy, it is necessary to exclude alternative accounts. Historically, three general types of alternatives have been offered. One invokes competition between incompatible reactions. The second possibility is that an inhibitory CS draws attention away from other excitatory stimuli and is merely an attentional distractor. The third is that reduced responding is not a matter of inhibition but rather of less excitation.

Rescorla (1969) argued that an inhibitory CS should acquire properties opposite to those of an excitatory CS, if inhibition involved learning that a CS and US were negatively correlated. One test designed to show the oppositional properties of an inhibitory CS was called *summation*. If a CS were truly inhibitory, it should reduce the probability that an excitatory CS would evoke its usual CR when the two stimuli were presented in compound for the first time. To rule out attentional distraction, the reductions obtained should be greater than those produced by a control CS that was uncorrelated with the US. Further evidence of inhibition would be shown by retardation of acquisition in which the inhibitory CS is transformed into an excitatory CS. The required finding is that conditioning should proceed more slowly than transformation of a neutral CS into an excitor. These two tests, taken together, are still accepted by most in the field as firm evidence of inhibition.

Equipped with tests for verifying the status of an inhibitory CS, researchers turned to the question of the psychological basis for behavioral inhibition. On the basis of Pavlov's work, one might speculate that an inhibitory CS signals a period during which the US is absent. This can be shown to be false. If two distinctive CSs are paired on separate trials with the same US, and both CSs together are then combined with a third CS and the triplet is reinforced, it turns out that the third CS acquires the properties of a conditioned inhibitor, even though it does not signal the absence of the US (Kremer, 1978). However, this procedure also suggests an answer. When two excitatory CSs are combined, unusually high levels of excitation are elicited—much higher than can be sustained by a single US. Hence, although the third CS does not predict the nonoccurrence of the US, it does predict that the single US received will be less than is predicted by the two excitatory CSs. Thus, conditioned inhibition seems to develop when the US received is less than that anticipated. This is currently the most accepted psychological account (Wagner & Rescorla, 1972).

Experimentation has also revealed that an extinguished CS does not actually lose its excitatory power as the term *extinction* suggests. Instead, the excitatory CS acquires a new inhibitory association that joins the already present excitatory association. That extinction does not erase the original excitatory association is abundantly clear if one reminds the animal of the earlier association. For example, if acquisition takes place in a different experimental context than extinction, a return to the context of acquisition causes *renewal* of the original CR (Bouton, 1993). Renewal is of obvious importance for our understanding and treatment of anxiety disorders. Conditioned fears are never truly lost (extinguished) but are only inhibited. It should be apparent from this last example that behavioral inhibition is a rich area for the application of basic research to psychological dysfunctions.

BEHAVIORAL MODELING

Much human learning occurs from sitting and watching, or from just happening to notice what someone else is doing. Indeed, more *social learning* occurs from observing others than from physically or verbally interacting and experiencing positive or negative outcomes. Observation provides information about what may be learned (alternative behaviors, potential consequences, etc.). When observation occurs under the right circumstances, it can result in immediate changes to learning or performance.

Modeling is defined as the process by which an individual (the model) serves to illustrate behavior that can be imitated or adapted in the behavior of another individual (the observer). It may also influence thoughts and attitudes. The model may be live; filmed; described in any other medium, such as print; or even imagined. The term *behavioral modeling* is distinguished from mathematical modeling and so on. Otherwise, the simpler term *modeling* is used.

When the observers are used as their own models, the process is called *self-modeling*. This process is procedurally very different, although there is a connecting theoretical thread (Dowrick, 1999; see encyclopedia entry "Video: Major Applications in Behavioral Science").

Applications

Modeling has been widely applied and evaluated in a variety of areas. Representative examples are described below under headings in six broad categories.

Professional Training

Modeling is often used in the training of human service personnel. For example, videotaped modeling has been used as a key component in training health care personnel to handle psychiatric emergencies and in training job coaches. Other popular training areas range from counselors to military special services, where it accounts for larger gains in skill acquisition than role-playing or feedback.

Social Skills and Daily Living

Modeling by in vivo demonstration is widely used as part of social skills training. Video modeling is the staple of many standard programs. It has been the primary component in a diverse range of training programs, from teaching young, isolated children to overcome their shyness, to providing alternatives to social behavior related to drug abuse, aggression, and other illicit or unhealthy activity. For example, films of age-appropriate students coping with social pressure to smoke cigarettes have been effective in programs at junior high schools. It may be noted that the programs with greatest effectiveness are those that illustrate adaptive coping (resisting coercion without destroying friendships), not negative consequences (early, gruesome death by cancer).

Parent and Child Issues

Different forms of modeling have been widely used in programs for parent training. While there is no substitute for realistic practice in acquiring skills for child care, it is equally clear that observing effective models is essentially valuable to begin such practice. Most parent training is requested because of the child's so-called problems. Therefore, children are taught communication and self-control skills as well. Modeling also proves effective for this purpose, using either peers or adults.

Preparing for Medically Related Treatments

The need to prepare people, especially children, for potentially invasive or scary treatment procedures has been extensively served by modeling strategies. Information (e.g., what steps are involved in the procedure) is important to emotional and long-term attitudes, but modeling is more essential to the immediate situation.

Physical Performance

Sport and other body coordination skills are widely taught using some form of demonstration by peers, coaches, and experts. Physical therapists also use modeling as the major component in rehabilitation through therapeutic exercises. The commercial video market is replete with examples, usually by experts, for the development of individual skills (golf, tennis, aerobics, skiing, etc.). Participants in team sports watch videotapes of opponents, not just to find weaknesses, but to seek out and imitate superior team playing strategies. Special effects (e.g., slow motion, still frames) in video modeling are most useful in motor performance applications.

Diverse Populations

Appropriately designed modeling has obvious application to individuals with disabilities and other diversity who may lack suitable models in their natural environment. Well-documented examples exist in the teaching of daily living skills, such as shopping by young adults with autism. Other types of skills for which modeling-based training has been developed include social skills, recreation, communication (e.g., sign language), vocational skills, and academics. Although it would seem best to use peers as models, often the models are expert adults from the dominant culture. Such demonstrations must be carefully constructed to match the individuality of the intended trainees.

General Principles

A modeling procedure focuses on the skill to be learned, its context, and its consequences. The modeled event is effective if the observer (1) absorbs the skill information, and later (2) has the opportunity, motive, and self-belief to use it (Bandura, 1997). Much research in the last 40 years has contributed to an understanding of these components.

The characteristics of the model contribute to the effectiveness of the procedure. The use of similar models, multiple models, and coping (as opposed to *mastery*) performances have been shown to assist effectiveness. These factors contribute to the ability of the viewer to absorb the skill information. They help to ensure that some of the skills demonstrated are attainable at an appropriate level of use by the observer.

When the model is similar, the observer will pay more attention and is more likely to be motivated to replicate the demonstrated behavior. Because the *activity* is important, behavioral similarity counts more than looks, social back-

ground, and so on, and unusual models, such as clowns, can gain attention without effective absorption of the skill information. The use of multiple models can boost the magnitude of effect and its generalization to other settings.

Coping (better called *struggling*) models are sometimes more effective than mastery models, who demonstrate only expert performance. High-status models can also be effective. These potentially contrary results are understood by considering how the modeled skills are relevant to the observer's ability level and how the specific model may contribute to motivation and sense of self-efficacy.

The characteristics of the observer and the setting also affect the efficacy of modeling. Sometimes observational learning must first be taught as a skill in itself—for example, young children with autism may not have learned to imitate others. Emphasizing a positive outcome or reward for the target behavior can enhance the effectiveness of a model. But it is important to note the frequent failure of negative modeling to act as a deterrent. The reverse is often the case, sometimes tragically. More than once, for example, televised dramatizations of teenage suicides, intended to be a deterrent, have been followed by increases in suicides of young people.

Modeling is well documented as a powerful intervention in its own right, but it is mostly used along with other procedures, such as opportunity to practice. It will normally take its place early in the learning sequence: basic information, *modeling,* practice, feedback, and feedforward. It can also be used as a sophisticated component in advanced learning applications.

BEHAVIORISM

Behaviorism was the most significant movement in experimental psychology for the first three quarters of the twentieth century. It was launched by Watson in 1913, but had already begun in the work of psychologists such as Thorndike and Pavlov, and it remains influential today despite an increasing chorus of criticism after about 1960.

The history of behaviorism is told elsewhere in this encyclopedia; this article is a rational reconstruction of the movement, focusing on psychological rather than philosophical behaviorism. The name *behaviorism* implies that there is only one kind of behaviorism, but this is far from the case. There have been many behaviorisms, and they can be classified and defined in several ways. Several rational reconstructions of behaviorism are therefore possible, and some are listed at the end of this article.

Mentalism: What Behaviorism Rejects

Prior to behaviorism, experimental psychologists studied the mind, which they defined as conscious experience, and their research tool was one or another form of introspection. Among themselves they disagreed over what counted as scientific introspection: Wundt insisted on a highly controlled form of self-report, whereas Titchener and the Würzburg group allowed retrospective analyses of mental processes, and William James advocated ordinary armchair introspection. They also disagreed about how to explain conscious experience. Some advocated a reductionist approach, in which experience was to be explained by reference to underlying physiological processes. Others preferred to cite unconscious mental processes as the cause of experience. Still others advocated pure phenomenology, in which experience was described but not causally explained. In any case, all were mentalists in taking mind as the subject matter of psychology to be investigated by introspection. Behaviorism rejects the mentalistic definition of psychology and, therefore, mentalism's research method of introspection. Behaviorists define psychology as the science of behavior, and they study behavior, eschewing attempts to enter their subjects' minds.

Varieties of Behaviorism

Classical Behaviorism

Historically, the most important distinction among versions of behaviorisms is that between Watson's original classical behaviorism—boldly stated but imprecisely worked out—and a variety of more sophisticated systems inspired by him, known collectively as *neobehaviorism.* In his paper "Psychology as the Behaviorist Views It," Watson (1913, p. 158) spelled out the fundamental faith of all behaviorists:

> Psychology as the behaviorist views it is a purely objective experimental branch of natural science. Its theoretical goal is the prediction and control of behavior. Introspection forms no essential part of its methods, nor is the scientific value of its data dependent upon the readiness with which they lend themselves to interpretation in terms of consciousness. The behaviorist, in his efforts to get a unitary scheme of animal response, recognizes no dividing line between man and brute. The behavior of man, with all of its refinement and complexity, forms only a part of the behaviorist's total scheme of investigation.

Watson sets out the essential contrasts with mentalism: The subject matter of psychology is to be behavior, not mind or consciousness; its methods are objective, and introspection is to be rejected; and behavior is not to be interpreted or explained by reference to mental processes. Watson laid down the behaviorist's creed, but although he continued to expound his own version of behaviorism (see his *Behaviorism*), the movement was taken in different directions by his successors, the neobehaviorists.

Methodological Versus Metaphysical Behaviorism

Philosophically, one must distinguish two main justifications for rejecting mentalism and choosing behaviorism. A methodological behaviorist concedes that mental events and processes are real, but maintains that they cannot be studied scientifically. The data of science, says the methodological behaviorist, must be public events, such as the motions of the planets or chemical reactions that all researchers can observe. Conscious experience, however, is necessarily private; introspection may describe it (often inaccurately), but does not make it public for all to see. Therefore, to be scientific, psychology must study only overt behavior and reject introspection. However real and however fascinating, consciousness, methodologically speaking, cannot be scientific psychology's subject matter. The exploration of subjective experience is left to the arts.

The metaphysical behaviorist makes a more sweeping assertion: Just as the physical sciences have rejected demons, spirits, and gods, showing them to be myths, so the psychologist must reject mental events and mental processes as mythical. This is not to say that mental concepts such as "idea" are necessarily meaningless (although they may be), any more than the concept "Zeus" is meaningless. We can describe Zeus and account for why people believed in him, while nevertheless asserting that the word *Zeus* never referred to anything that ever existed. Similarly, says the radical behaviorist, we can describe the conditions under which people use "idea" or any other mental concept, and account for why they believe they have minds, and still assert that "idea" or "mind" and so on do not refer to anything that really exists, except perhaps certain behaviors and certain stimuli. Therefore, psychology must be behavioristic because there is no mind to investigate: Behavior is all there is.

Watson's own position is unclear. He typically defended behaviorism on methodological grounds but, especially in his later writings, asserted the metaphysical claim, too. The various neobehaviorists came down on different sides.

Varieties of Neobehaviorism

Once begun by Watson, the movement of behaviorism—like all movements—was changed by its later adherents. The major varieties of neobehaviorism are formal behaviorism, including logical behaviorism and purposive (or cognitive) behaviorism; informal behaviorism; and radical behaviorism. All but the last are forms of methodological behaviorism; radical behaviorists uphold metaphysical behaviorism.

Formal Behaviorism. While the behaviorist takes the subject matter of psychology to be behavior, he does not necessarily rule out talking about unobserved processes that may be used to explain observed behavior. Indeed, under the influence of logical positivism and operationalism the formal behaviorist made it his job to explain observed behavior in terms of a theory consisting of just such unobserved entities. However, these entities were not conceived as mental processes actually taking place in a person (or animal) and perhaps accessible to introspection, but were defined *behavior-theoretically;* that is, a given unobserved theoretical construct was operationally defined in terms of either manipulations performed on the animal or some aspect of its stimulus environment, or a measurable aspect of its behavior. In this way formal behaviorists hoped to gain scientific status by accepting methodological behaviorism, while aspiring to the same kind of explanatory theory found in physics or chemistry, where unobserved theoretical terms are commonplace.

The logical behaviorism of Hull and his associates was the most completely developed program of formal behaviorism. Following the lead of Newton and physics generally, Hull set out a hypothetico-deductive learning theory proposed to be valid for all mammals. The theory was stated as a set of axioms from which, via operational definition, predictions about behavior were derived that could then be put to the test.

To exemplify the method, consider the following (simplified) axiom from Hull's *Principles of Behavior* (1943):

$$ {}_{S}E_{R} = {}_{S}H_{R} \times D $$

or in words, *reaction potential* (${}_{S}E_{R}$) is equal to *habit strength* (${}_{S}H_{R}$) times *drive* (D).

Reaction potential refers to the momentary tendency of an organism (e.g., a rat) to make a particular response (e.g., run down an alley). It may be measured, or operationally defined, in several ways, including latency (how long after we let him go does he get started), speed, strength (how much weight will he pull to get to the other end), or resistance to extinction of the response. The concept of habit strength claims that, when an organism learns something, it is learning something we cannot see except for when it happens to occur—namely, as a habit—and that the strength of the habit may be great or small. Operationally, habit strength was defined in terms of the number of times the organism has been reinforced for making a response such as running down an alley and finding food at the other end. Finally, drive refers to the motivational state of the organism and may be operationally defined in terms of number of hours without food or water. In doing an experiment, we can manipulate the values of ${}_{S}H_{R}$ and D, predict the

value of ${}_{S}E_{R}$, measure its actual value, and check the prediction with the result.

The expressions ${}_{S}E_{R}$, ${}_{S}H_{R}$, and D are theoretical constructs or intervening variables. We do not observe reaction potential, habit strength, or drive directly; rather, we define them on the basis of what we do to the organism or on the basis of our measurement of its behavior. The theoretical strategy of formal behaviorism, then, is to permit theorizing about unobservable entities as long as one does not conceive of them mentalistically as something the organism has inside. Instead, theoretical constructs should be conceived of as intervening variables defined over stimuli and responses.

Tolman's purposive or cognitive behaviorism, when contrasted with Hull's logical behaviorism, shows how different two behaviorisms can be in detail while retaining allegiance to Watson's broad creed. Tolman rejected the mechanistic "muscle-twitchism" of Watson and Hull. For them, learning consisted in associating certain stimuli with specific motor responses, thus eliminating reference to purpose or cognition, which they regarded as mysterious and mentalistic. Tolman, on the other hand, conceived of behavior as ineluctably purposive (in that animals are always acting to move toward or away from some goal) and of learning as ineluctably cognitive (its purpose being not to respond to stimuli, but to learn about one's environment).

Nevertheless Tolman, like all behaviorists, shunned introspection and the study of consciousness. He constructed a theory that was much less fully elaborated than Hull's, despite the fact that it was he who introduced intervening variables to psychology. Tolman claimed that purpose, cognition, and expectancies could be defined theoretically through behavior. Tolman maintained that purposiveness was a property of behavior itself, or it could be treated as an operationally defined intervening variable.

Therefore, although Hull's and Tolman's learning theories were ever at odds, both are different theoretical and research strategies carried out within methodological, formal behaviorism. Following Watson, they abandoned mentalism for the objective study of behavior and, following the logical positivists, constructed theories of learning containing unobserved but nonmental, operationally defined theoretical constructs.

It needs to be said, however, that while Hull and Tolman theoretically followed operationalist and logical positivist guidelines, each one deviated sharply from them. Hull had a secret agenda to create a learning machine, and his theory was a description of that machine dressed in postulate form. Although Tolman, too, talked like a logical positivist, he thought of cognitive maps and expectancies as real things inside organisms' heads, not just as operationally defined constructs having no reality beyond theoretical convenience. In a narrow sense, then, neither Hull nor Tolman was a practicing formal behaviorist, because their theories were about something other than behavior: for Hull, the processes inside his learning machine, and for Tolman, cognitive processes inside living organisms. Their followers were truer to the behaviorist creed.

Informal Behaviorism. In any case, after the golden age of theory in the 1930s and 1940s, behaviorism went through further evolution. This was more true of Hull's logical behaviorism than of Tolman's purposive behaviorism, because Hull had more followers and left behind a more fully developed theory. The neo-Hullian behaviorism of the post–World War II era is sometimes called neobehaviorism, but a more descriptive phrase would be informal behaviorism or "liberalized Stimulus-Response theory." The major hallmark of the movement was lessened concern with axiomatic grand theory and increased willingness to talk about the higher mental processes in human beings, if done in S-R mediational terms. Formal behaviorism thus became less rigidly formal and more flexible in handling important human phenomena such as language and problem solving.

The informal behaviorists developed one of Hull's notions into a central cognitive process. Hull had explained some learning phenomena by postulating that organisms sometimes make fractional, unobservable responses (r) which have stimulus consequences (S), so that part of a learned S-R behavior chain is covert: S → r → s → R. Hull conceived mediating r-s pairs as covert peripheral responses (e.g., a rat might slightly salivate at even the beginning of a well-learned maze). The informal behaviorists, including Miller, Berlyne, Kendler, and Kendler, conceived r-s pairs as central brain processes that nevertheless followed the usual laws of S-R learning, and so could be incorporated into operational S-R theories of learning with no abandonment of behaviorism.

The informal behaviorists were thus able to talk about thinking, memory, problem solving, and language in S-R behavior theory terms, treating them as covert parts of learned S-R connections. In this way the range of behavior explicable in S-R terms was increased. A notable result was social learning theory, a marriage of neo-Hullian behaviorism and psychoanalysis, with some of Freud's postulated mental mechanisms being treated as covert mediating behaviors.

Historically, informal behaviorism has proven less a substantive position than a bridge from formal behaviorism to more cognitive, information-processing viewpoints. Once permitted to step inside the organism, as the central mediating response allowed behaviorists to do, there is little reason to think of the brain as an S-R device beyond mere prejudice in favor of S-R language. Once the prejudice is overcome, the attraction of the increased flexibility of information-processing language, accompanied by no loss of theoretical vigor, becomes irresistible. Whether one ceases to be a behaviorist upon giving in is an open question.

Radical Behaviorism. The purest form of behaviorism is Skinner's radical behaviorism—essentially the same as the

less-well-known interbehaviorism of Kantor. Skinner rejected methodological behaviorism for the more radical assertion of metaphysical behaviorism: Mind and mental talk are cultural myths to be exploded and discarded.

Methodological behaviorists identified the mental with the private and made the latter off-limits for science. Skinner rejected the identification, recognizing that private events must figure in scientific psychology. A toothache is a private event, or stimulus, that powerfully controls one's behavior, leading one to take aspirin and visit the dentist. Radical behaviorism does not therefore reject an organism's private world, but studies it scientifically. However, it is a behaviorism because it rejects the mind and aims at the prediction and control of behavior.

Ordinary, everyday mentalistic talk is explained in three ways. First, some alleged mental events like toothaches are really just physical processes in the body that we have learned to label. There is no difference in principle between a public stimulus like a pinprick and a private one like toothache except that one person alone has access to the latter event. Second, some mental events, especially feelings, are just collateral by-products of environmental influence and resulting behavior but play no role in determining behavior. So one may "feel satisfied" if praised by one's boss, but what controls the behavior is the praise itself—the reinforcer—and not the collateral feeling. Unlike private stimuli, which may exert control over behavior, collateral feelings do not, and they may be ignored by scientific psychology, however much they fascinate the phenomenologist. Finally, many mentalistic terms are simply rejected outright as myths, being regarded as verbal operants taught by our culture and entirely devoid of reference. So, for example, free will is regarded as a myth (since all behavior is determined), invented largely in the Enlightenment as a reaction to the pain control used by oppressive, authoritarian governments. Such myths Skinner and his followers regard as dangerous because they stand in the way of effective application of behavioral technology and a scientific pursuit of happiness.

In its essence, though not at all in its details, radical behaviorism is the closest of all the neobehaviorisms to Watson's classical behaviorism. For the radical behaviorists, as for Watson, talk of mind is something to be exorcised by all, not just by scientists, as a relic of our superstitious, prescientific past. With positivism, radical behaviorists assert that whatever cannot be observed does not exist and that the world and its people would be better off abandoning comforting illusions to face bravely the material facts of life. Mind, they hold, should go the way of Zeus, Odin, and the imaginary friends of our childhood.

Behaviorism Today

Radical behaviorism is the only behaviorism exerting serious influence today. It has its own division within the American Psychological Association and its own journals, *The Experimental Analysis of Behavior* and *Applied Behavior Analysis.* The other behaviorisms have passed into history, their founders' intellectual descendents having altered them beyond recognition.

But behaviorism as a philosophy and an historical movement remains an object of interest to psychologists, philosophers, and historians. An important unresolved question is the current status of behaviorism. Although formal and informal behaviorism are clearly gone and radical behaviorism's importance is waning, it is clear that there has been no return to prebehavioristic mentalism. Cognitive psychologists still aim for the prediction and control of behavior, reject introspection for objective methods, have relatively little to say about consciousness, and study both humans and animals (as well as computers). In other words, they still could subscribe to Watson's basic creed, while rejecting his "muscle-twitchism" as did Tolman and the informal behaviorists. It is possible, then, that cognitive psychology is a new form of behaviorism with historical roots in Tolman's purposive behaviorism and Hull's fascination with learning machines. Or, if one insists that cognitive science's willingness to postulate real inner processes sets it off sharply from behaviorism, perhaps a new term is needed that encompasses both behaviorism and cognitive science, distinguishing both from traditional mentalism. Edmund Ions has coined a possible name: *behavioralism.*

BELIEF IN A JUST WORLD

The Concept

The belief in a just world (BJW) refers to beliefs and processes that convey and maintain faith in the idea that the

world is a fair and just place, a place where people get what they deserve and deserve what they get—a concept first described by Melvin J. Lerner in the 1960s. Lerner's interest in the concept came from his efforts to understand why highly educated university students consistently condemned victims of poverty as "lazy and no good," while denying evidence showing them to be victims of socioeconomic powers beyond their control. According to Lerner, in order to maintain psychological equanimity, engage in goal-directed behavior, and plan for the future, people need to believe that they live in a just world, a place where they will get what they deserve, at least in the long run.

The BJW serves several functions. First, it helps reduce existential terror (i.e., concerns resulting from our ability to comprehend a meaninglessness world and our own mortality). Specifically, without assurance that victims deserve their fates or that they will ultimately be compensated, people would be overcome by the suffering that surrounds them and be terrified that a similar fate could befall them. Second, the BJW encourages people to commit to long-range goals and facilitates the socially regulated behavior of day-to-day life. The belief encourages goal-directed, instrumental behavior by providing the rationalization necessary to engage in such behaviors. Specifically, without the knowledge that hard work will be rewarded, there is little rationale for exerting such effort. Finally, the belief that violators of societal regulations will be punished helps people to feel safe and keeps society orderly.

Maintenance Process and Reactions to Injustice

According to Lerner, instances of injustice arouse strong emotional reactions and defensive coping reactions. Typical emotional reactions range from empathic pain, concern, or pity, to revulsion, fear, or even panic (Lerner, 1980). People have developed sophisticated ways of warding off such negative emotions and maintaining their belief in a just world. Lerner outlines *rational* and *nonrational* strategies that function to eliminate or neutralize threats to the belief in a just world. Rational strategies include prevention and restitution. Here, social devices (e.g., social agencies) or one's own efforts may prevent injustice, restore justice, or at least compensate the victims of injustice. Acceptance of one's limitations is a cognitive strategy where the individual convinces him- or herself that if given infinite time and resources, justice could have been achieved; however, there is only so much that one person can do.

Nonrational strategies include denial of and withdrawal from the unjust situation and several varieties of cognitive reinterpretation, including reinterpretation of the outcome, reinterpretation of the cause, and reinterpretation of the character of the victim. Denial involves selective perception of the environment so as to avoid evidence of injustice, whereas withdrawal involves physically removing oneself from areas of potential injustice or, as a preventative measure, structuring one's life so as to avoid situations likely to reveal injustice. Overall, reinterpretation strategies involve reevaluating an unjust situation in a way that removes the injustice. Reinterpretation of the outcome may involve maintaining that unjust suffering promotes long-term benefits, that suffering makes one a better person, or that some people are happy in their suffering. Reinterpretation of the cause, or behavioral blame, refers to attributing the victim's fate to something he or she did or failed to do. Thus, justice would have prevailed, if only the victim had done the right thing. Finally, reinterpretation of the character of the victim, or characterological blame, refers to denigrating the personality of the victim so as to make him or her the type of person who deserves his or her unjust fate.

Lerner contends that people also develop long-term strategies to maintain BJW. Such strategies include developing a sense of ultimate justice, where despite short-term setbacks, justice wins out in the long run or where victims are compensated (or punished) in the afterlife. People may also compartmentalize cultures or subcultures into just and unjust ones. Therefore, not all cultures need be just, and injustices are acceptable and not personally threatening as long as they occur outside one's own culture.

Research on Belief in a Just World

Research on the BJW remains strong. Furthermore, and as a testimony to his original insight, Lerner's theory remains largely unchanged from his original statements. Theoretical advancements have been at the margins: What are the boundary conditions for belief in a just world? Are there multiple just and unjust worlds? What is the nature of the person who believes in a just world?

Overall, research on BJW falls into one of several categories. For example, a large number of studies have examined how people cope with injustice, including how they react emotionally, behaviorally, and cognitively to victims of injustice. Included are investigations of behavioral and characterological blame, with victimized groups including victims of rape or incest, the homeless, victims of spouse abuse, members of stereotyped groups, and people with diseases such as cancer or AIDS. A second category of research examines the role of BJW in other social processes. Included are studies examining how BJW relates to perceived risk assessment, facilitates coping with acute stress, is associated with life and marital satisfaction, contributes to practice of health behaviors, is associated with investment in long-term goals and motivation, relates to religiosity, and predicts recovery from illness. In contrast to the victim derogation work, these studies usually assess the adaptive side of BJW. A final category of research includes studies of the nature of the belief (e.g., is there a just world for self versus for others?), development and revision of individual difference measures, studies of the relation of BJW to political beliefs and ideologies, and cross-cultural studies of BJW.

BELL-MAGENDIE LAW

The Bell-Magendie Law refers to the discovery, in the early 1800s, that sensory nerves enter the spinal cord by way of the dorsal roots of the spinal nerves, and motor nerves exit the spinal cord by way of the ventral roots. Recognition for making the discovery was attributed jointly to Charles Bell and François Magendie. Prior to this observation, it was held that nerves were tubular conduits that served both sense and motor functions. The discovery of functionally distinct sensory and motor nerves revealed, for the first time, clear evidence of the basic structure of the nervous system. Articulation of the physiology of the spinal reflex arc and the architecture of the nervous system in terms of the specific function of sensory and motor nerves developed directly and swiftly from this first fact of neural localization.

Charles Bell (1774–1842) was an accomplished Scottish anatomist and surgeon. In 1811, he wrote a pamphlet titled *Idea of a New Anatomy of the Brain: Submitted for the Observation of His Friends.* The pamphlet was privately printed and distributed to 100 friends and colleagues. In this letter, he outlined a rationale for the study of brain function, and he speculated about the location of higher mental functions in the brain. He considered that the functions of specific nerves were determined from their origin in different parts of the brain. During this discourse, he noted that spinal roots emerging from the vertebra fused together to form larger nerves. His opinion that these spinal nerve roots were functionally distinct was put to the test in a simple experiment. When he severed the posterior (dorsal) root, the muscles of the back did not convulse, but he observed a convulsion of the muscle when he touched the anterior (ventral) root.

In 1822 François Magendie (1783–1855), a French physician and physiologist, published his findings from experiments in which he cut unilaterally some of the posterior spinal roots, anterior spinal roots, or both posterior and anterior roots. Magendie had devised a clever procedure that enabled him to cut anterior roots without damaging the posterior roots. He noted that sensation (pain) was not elicited when the severed posterior root was touched, whereas the limb moved spontaneously when the anterior root was intact. Severing the anterior roots, however, caused the limb to go flaccid, whereas sensibility remained when the posterior root was intact. Magendie concluded that the anterior and posterior roots of the nerves emanating from the spinal cord have different functions, with the posterior root pertaining to sensibility, whereas the anterior root was linked to movement.

Following the publication of Magendie's article in 1822, a challenge to the priority of the discovery was issued by Charles Bell, and subsequently by his brothers-in-law John Shaw and Alexander Shaw in various texts and journals. Bell's unpublished 1811 pamphlet was cited as the basis for his claim to be the first to establish that sensory and motor nerves were distinct entities. This campaign to assign priority for the discovery to Bell was quite successful. Bell was lauded for the discovery by many eminent physiologists and scholars throughout the nineteenth century, such as Sherrington, who made seminal contributions to the physiology of spinal reflex arcs; Neuberger, a respected medical historian; and even by some of Magendie's contemporary French physicians, such as Flourens. Scholars who have more recently examined documents relevant to the discovery, however, dispute Bell's claim for priority.

An analysis of the controversy was thoroughly documented by Cranefield (1974), in a text that includes a facsimile of Bell's annotated letter to his friends, as well as facsimiles of all of the material by Bell, John Shaw, and Magendie on which the claim for priority can be based. Clearly, there is no challenge to Magendie's experiment that is precise, elegant, and unambiguous in demonstrating, and correctly interpreting, the sensory function of the posterior spinal root and the motor function of the anterior spinal root. Several issues were raised that cast aspersions on Bell's claim. That Bell's pamphlet was privately printed and circulated, rather than published in a scientific journal that was open to public scrutiny, certainly detracts from the authority of discovery. Second, during the period from 1816 to 1823, Bell and John Shaw published numerous articles on the anatomy of the brain and nerves, but in none of these was there a specific statement about the functions of the spinal nerve roots. This indifference is in marked contrast to the importance of the discovery claimed by Bell after Magendie's publication in 1822. Finally, following the procedure described in *Idea of a New Anatomy of the Brain* (Bell, 1811/1974), there was no basis for suggesting the sensory function for the anterior spinal roots.

BENDER GESTALT

The Visual Motor Gestalt Test was developed by Lauretta Bender in 1938. Both conceptually and methodologically, the test was heavily built on concepts and materials derived from the founders of Gestalt psychology: Max Wertheimer, Kurt Koffka, and Wolfgang Köhler. "The gestalt function may be defined as that function of the integrated organism whereby it responds to a given constellation of stimuli as a whole; the response itself being a constellation, or pattern, or gestalt" (Bender, 1938, p. 3).

Stimuli

Bender (1938) carefully chose nine of Wertheimer's (1923) original designs for the Visual Motor Gestalt Test on the basis of principles (laws) put forward by the founders of Gestalt psychology.

Administration

The ease of administration of the Bender Test certainly contributes to its popularity among psychologists. Variations in administration procedures, however, are not uncommon even for the standard administration (Lezak, 1995). Other modalities of test administration include the stress modality, which involves the repetition of the test under the stress of time pressure, as described by Lezak (1995) and standardized by Brito and Santos (1996), and the immediate and delayed recall of all designs collectively, as reported by Brito, Alfradique, Pereira, Porto, and Santos (1998) in an extensive normative study.

Scoring Procedures

Bender (1938) used her test mainly as a clinical tool to observe the performance of her patients. Nevertheless, several scoring procedures were developed over the years to tap into the potential of the test to assess visuoperceptive cortical functions or as a projective technique for the study of personality.

The best known scoring procedure seems to be the one devised by Pascal and Suttell (1951) who identified over 100 scorable characteristics of the Bender Test in adolescents and adults. Keogh and Smith (1961) and Koppitz (1975), among others, devised scoring systems for kindergarten and elementary school children. Furthermore, Koppitz (1975) included emotional indicators in the analysis of test protocols. Other researchers have developed scoring procedures centered on whole performance rather than on the analysis of individual reproductions. A prototypical example of such a scoring system would be the Psychopathology Scale devised by Hutt (1985). Hutt, in addition, developed another scale that taps into the projective potential of the Bender Test: the Adience-Abience Scale.

Test Properties

Developmental studies on the Bender Test have shown that age, social class, cultural factors, ethnic group, and academic standing impact significantly on test performance (Koppitz, 1975; Brito et al., 1998). Additionally, developmental Bender and IQ test scores are significantly correlated, but only within the average and below-average IQ range (Koppitz, 1975). The finding of Brito and Santos (1996) that the number of emotional indicators significantly correlates with factor scores derived from the Composite Teacher Rating Scale (Brito & Pinto, 1991) suggests that the number of emotional indicators is a valid measure.

Bender Test and Child Neuropsychopathology

Bender (1938) reported on the abnormal test productions of Francine, a schizophrenic child. Additionally, the Bender Test has been used in the identification of children with learning difficulties (Koppitz, 1975), determination of the neuropsychological correlates of hyperactivity and inattention in school children (Brito, Pereira, & Santos-Morales, 1999), and neuropsychological assessment of the effects of stimulant medication (Brown & Borden, 1989) and biofeedback training of children with Attention Deficit/Hyperactivity Disorder (Hodes, 1989).

Bender Test and Adult and Geriatric Neuropsychopathology

Bender and the Gestalt psychologists considered that pathological integrative dysfunctions would be revealed by ruptures or modifications in the final products of the visual motor reproductions of the original stimuli. Bender (1938) presented a significant amount of information on the abnormal test results of patients with Schizophrenia and manic depressive psychoses. Furthermore, Bender (1938) showed that patients with organic brain disease (e.g., aphasia and Korsakoff syndrome) also produced abnormal reproductions of the test stimuli. Lezak (1995) considers that poor performance on the test is most likely in patients with right parietal lesions, although a normal performance cannot be construed to rule out organic brain pathology.

Flexible and creative adaptations for the administration of the Bender Test will guarantee its continued use as a valuable tool in the clinical behavioral neurosciences.

BETA AND GAMMA RHYTHMS

Beta and gamma rhythms were first studied in the human electroencephalogram (EEG) recorded from the scalp. Beta rhythm is defined in general as any EEG rhythm over 13 Hz (The International Federation of Societies for Electroencephalography and Clinical Neurophysiology [IFSECN] 1974). Typically, it is a rhythm from 13 to 35 Hz. Gamma rhythm is commonly used by neuroscientists to designate neural activity of frequency of about 30–100 Hz, including the 40-Hz oscillations. Beta and gamma EEGs are of relatively low amplitude (less than 30 μV) in the EEG, and their quantification normally requires computer analysis with careful separation of muscle artifacts (Niedermeyer, 1999).

Three main types of beta rhythms are commonly observed in the scalp EEG of human adult subjects: (1) a fronto-central beta rhythm that can be blocked by contralateral movement or tactile stimulation, (2) a diffused beta rhythm without specific reactivity, and (3) a posterior beta rhythm that can be blocked by visual activity, similar to the occipital alpha rhythm (Kuhlo, 1976). An increase in beta rhythm has been reported in neuropsychiatric patients, but Kuhlo (1976) concluded that "no adequate evidence exists at present of any relationship between normal or excessive beta activity and psychiatric disorders." A pronounced increase in beta-frequency EEG was found with drugs that enhance gamma-aminobutyric acid-A (GABA-A) receptor functions, including sedative doses of barbiturates and benzodiazepines (Kozelka & Pedley, 1990) and the anesthetic propofol. Neural circuitry that involves GABAergic interneurons in the cortex is probably responsible for the generation of the drug-induced beta and gamma rhythms (Leung, 1998; Traub, Jefferys, & Whittington, 1999). The regional loss of the spontaneous or the barbiturate-induced beta rhythm is a sign of local cortical dysfunction.

After Jasper and Andrews (1938), the term *gamma rhythm* has not been adopted for use in clinical EEG (IFSECN, 1974). The recent interest in gamma rhythm stems from animal experiments that have shown the importance of gamma rhythm in sensory information processing in the brain (Freeman, 1991; Singer & Gray, 1995). In the visual cortex, single neurons may code for various features of a visual object, like size, form, and orientation. It is proposed that the spatially dispersed neurons that code for different features may synchronize through gamma oscillations, thus forming a dynamic assembly of neurons that represents an object uniquely (Singer & Gray, 1995). Similar processes may exist in the olfactory, auditory, somatosensory, and motor cortices. Gamma rhythms have also been found in subcortical structures, including the thalamus (Ribary et al., 1991; Steriade, Contreras, Amzica, & Timofeev, 1996) and basal forebrain nuclei. In the hippocampus, gamma waves may mediate neural processing and enhance interactions among the entorhinal cortex and various subfields of the hippocampus (Leung, 1998; Bragin et al., 1995). An increase in hippocampal gamma waves after seizure or phencyclidine is thought to drive behavioral hyperactivity, a feature of psychosis in animals (Ma & Leung, 2000; Ma &

Leung, 2002). Gamma waves are implicated in the maintenance of consciousness (Engel & Singer, 2001), and gamma waves are suppressed during general anesthesia (Traub et al., 1999; Ma, Shen, Stewart, Herrick, & Leung, 2002).

Multiple mechanisms underlie the high-frequency oscillations in the brain. Synaptic interactions among excitatory and inhibitory neurons (Freeman, 1991) or among inhibitory interneurons only (Traub et al., 1999) have been purported to generate gamma oscillations. Llinas, Grace, and Yarom (1991) discovered that single neurons may oscillate at various frequencies including beta and gamma frequencies. In the brain, local neural circuits generate beta or gamma activity that may synchronize with other local and distant circuits. Many parts of the brain respond preferentially to gamma rather than other frequencies, and thus temporal synchronization across spatially distributed domains may be achieved dynamically.

BIOFEEDBACK

Biofeedback is best understood as a closed feedback loop consisting of a person or other animal, a response, a means to detect the response, and a mechanism for displaying the response to the person or animal—the response is thus fed back. For example, a person can be instructed to increase his or her heart rate; the heart rate is displayed by a monitor and fed back to the person; a feedback loop is thereby established. Biological systems have numerous, reflexive feedback loops to maintain homeostatic integrity—for example, body temperature, blood sugar, blood pressure, and endocrine levels. Fluctuations are kept within narrow limits by such feedback loops. However, biofeedback learning is not reflexive; it is more closely associated with higher-order learning processes.

One motive for the development of biofeedback was to devise therapies for volitional control over processes considered automatic and reflexive. Processes such as heart rate, blood pressure, and gastric secretion change along their respective dimensions, depending upon metabolic needs and emotional states. But when such processes move beyond certain limits, then health and proper functioning of the organism become compromised. Biofeedback self-regulation, as a therapy, can be viewed as a learning technique to help keep systems within proper limits with little of the side effects of more traditional medical therapies. A second stimulus for biofeedback development came from theorists concerned with disproving the hypothesis that responses innervated by the autonomic nervous system were not modifiable by reward learning. This position held that such responses were capable of being modified only through the conditional response techniques crafted by I. P. Pavlov.

A third reason for exploration came from interest in the self-control of conscious states. The fact that electroencephalographic (EEG) rhythms might be modifiable by providing information to an observer regarding EEG activity led to increased biofeedback research. Finally, the idea that self-regulation of neuromuscular function might help alleviate certain types of pain, such as headache, or lead to recovery of muscular function following trauma or disease, further helped the development of biofeedback.

Early experimental reports indicated that human subjects could control vasomotor responses, electrodermal activity, and heart rate. In the first of these studies a Russian investigator, Lisina (in Razran), claimed that when individuals were allowed to view a polygraph displaying their vasomotor responses to electric shock, they learned to produce vasodilation to escape the shock—the usual response to cutaneous electrical stimulation is vasoconstriction. Following these early studies, a number of laboratories began publishing data claiming to have effected reward learning in a variety of autonomically mediated responses with both humans and animals. Besides the usual methodological objections, criticism centered on the mechanisms responsible for the learning. A mediation issue was proposed that held that true reward learning was not occurring. Instead, it was argued, the subjects were somehow mediating the autonomic response through either cognition (i.e., thinking either calming or emotional thoughts) or covert striate muscular activity (either intended, with no movement, or actual, with movement). Although this issue remains unresolved, studies on subjects paralyzed by spinal lesions and plagued by hypotension indicated that neither cognitions, small muscular twitches, nor actual movement could account entirely for the biofeedback-produced changes. Autonomic reward learning is also influenced by such variables as type of feedback, awareness, instructions, homeostatic restraints, and links between somatic and autonomic response systems.

Biofeedback has been applied to athletic performance, Raynaud's disease, cardiac abnormalities, migraine headache, functional diarrhea, tension headache, temporomandibular disorder, essential hypertension, diabetes mellitus, Attention-Deficit/Hyperactivity Disorder, gait disorders, urinary incontinence, nocturnal enuresis, irritable bowel syndrome, tinnitus, fibromyalgia, and asthma, as well as to other problems with autonomic involvement such as anxiety, eczema, and sexual arousal. The applications continue to expand, and biofeedback is, in fact, the method of choice in treating Raynaud's disease.

The application of biofeedback techniques to problems resulting from neuromuscular dysfunction has shown considerable promise. Many reports are available on a wide array of disorders, ranging from headache to foot drop. Neuromuscular feedback has shown impressive specificity of control by successfully training subjects to either activate or inhibit activity of single motor muscle units as well as to control fecal incontinence.

Attempts have been made to modulate EEG activity through either biofeedback or manipulation of cognitive states thought to underlie a specific range of EEG frequencies. Results of these studies showed that biofeedback for alpha (8–12 Hz) did change and was accompanied by changes in psychological state. Increased alpha was related to feelings of relaxed attention and absence of anxiety. Whether increases in alpha produced psychological changes or the psychological states produced the EEG changes became part of the mediation issue. Evidence available strongly implicates the role of eye movement in the production or suppression of alpha, and this oculomotor hypothesis is the most salient explanation regarding alpha control. Convergence, divergence, and focusing of the eyes are related to the amount of alpha produced. In addition, correlated psychological states with such changes are at least partly due to expectations. Attempts have also been made to relate theta EEG (4–7 Hz) to the psychological states of dreamlike imagery and creative insight. Finally, some research has focused on modification of the sensorimotor rhythm (12–14 Hz) to reduce epileptic seizures. Results showed that when modification occurred in the 6–8-Hz band there was a concomitant reduction of seizures.

BIOGRAPHICAL DATA

Biography—the writing of a life (from Greek *graphein* and bio)—is an ancient concern of humankind. *The Odyssey,* the Bible, and Plutarch's *Lives* provide examples. In everyday life even a short conversation on meeting a person is probably going to include questions about background. Professionals working with people obtain histories of health events, employment, and education. In psychological lore, it is often said that the best predictor of future behavior is past behavior—especially under similar circumstances. Despite this widespread and age-old interest, there are no widely accepted tests or inventories and little psychological

research using systematic scoring of personal histories over the life span.

Five major sources for constructing possible scores or indexes from life-history data are the following: (1) interviews with the target person and his or her acquaintances; (2) written biographies and autobiographies; (3) personal documents and products such as diaries or works of artists and others; (4) institutional records such as hospital charts, application forms, and school records; and (5) specially constructed biographical inventories and checklists. The first four are mainly used impressionistically and informally, but they may be quantified by judges counting frequencies of specified events or by rating or coding the nature of the material. As an interesting example, Gordon Allport in his 1965 *Letters from Jenny* coded for emotions and thoughts the 301 letters written when Jenny was aged 58–70.

Organizational and industrial psychologists have taken the lead in biodata research, often using standardized application blanks quantified by attaching weights to items. As early as 1894, an insurance company used standard forms for selecting salespeople. Later, military and industrial psychologists developed forms. In World War II, psychologists demonstrated good validity, with coefficients ranging from 0.25 to 0.45, in predicting success in training U.S. pilots, navigators, and army officers. Weights of items on a biodata form, sometimes called a *biographical information blank* (BIB), can be validated against outcome criteria such as supervisors' ratings or productivity. Such a biodata score may contain a variety of items, such as marital status, previous job tenure, health conditions, or hobbies. Care must be taken to specify the relevance of items to the position and to avoid misleading or illegal bias from background factors, such as minority status, sex, age, or disability.

A biographical inventory or checklist is a set of items representative of life-history events or experiences that are pertinent to the purpose of assessment. Psychometric techniques using such indicators as health status, social adjustment, and job success will select and weight items. Items on inventories emphasize factual events or conditions, but some items may verge on the attitudes and subjective impressions found in personality inventories. All of these self-report procedures are subject to the usual criticisms of the reporting of life histories, such as poor recall, intentional or unintentional distortion, and various test-taking attitudes. Especially if biographical items are transparently related to the situation of assessment, subjects may slant responses, for instance, to get a job or to avoid incarceration. These problems are similar to those found on all self-report inventories. Intensive interviewing compared with checklists and inventories would improve accuracy of reports, but interviews take costly professional time.

Personality inventories often include life-history items, but there are few published inventories specific to biography. Child development tests and inventories cover only part of the life span. For adults, the Minnesota-Briggs History Record provides seven scales having titles such as "Social Misfit" and "Introversion." There is also a verbal projective technique, Bruhn's Early Memories Procedure, which, however, produces no scores. Another more limited approach is that of checklists and inventories of life changes on which subjects indicate whether they have had various stressful events, but these refer only to the last few weeks or months and are not life histories. Clinicians may use the informal technique of having clients draw a lifeline marked by major shifts or decisions for better or worse. As life span theory develops and recognizes the changing conditions surrounding the person, it seems likely that inventories and other procedures will be produced to measure important variables over a long period of time. Until then we will depend mainly on reported life stories, often very interesting, but judged impressionistically. Some psychologists, instead of pursuing factual life histories, frankly acknowledge that much of what passes as life history is really narrative and should be analyzed as stories are.

BIOLOGICAL CLOCKS AND SEASONAL BEHAVIOR

The biological rhythms, detectable at all levels of organization, constitute a temporal structure in all animal species. These rhythms concern many biological parameters and have clinical implications, mainly in psychiatry.

Human rhythms are determined by endogenous pacemakers, which are located in the hypothalamus. The hypothalamus is in interrelation with other elements of complex human biology such as the endocrine system, which is affected, via the cortex cerebri, by environmental factors such as light, darkness, seasons, noise, food, and stress. Thus, endogenous pacemakers adapt their impulses to other environmental rhythms. These complex interferences regulate our biological clocks. A dysfunction of one factor may induce a rhythm modification, which alters another rhythm, and so on, and may result in a clinical disorder, often a psychiatric illness. In this manner, our living patterns are controlled by the interrelation between endogenous pacemakers and exogenous rhythms.

The biological rhythms of different functions become apparent at different times after birth. In the infant, the development of rhythmicity must represent a combination of the genetic potential of the maturation process in the brain and of the varying influences of environment. The alternation of light and darkness is perhaps the most obvious of external rhythms, but similar alternations of noise and silence and the attention that the infant receives from adults may also be of importance. In the adult, the biological rhythms are represented by the periodic regular cyclic variations of the biological processes, describing a sinusoidal function with individual characteristics of periodicity and amplitude.

The human rhythms are represented mainly by circadian and circannual rhythms, characterized, respectively, by a period of 21 to 27 hours and a longer period of more than 27 hours, such as a month or season. The human circadian system is composed of at least two oscillators, which are self-sustained and coupled to each other. One of these oscillators is strong and controls body temperature, REM-sleep propensity, and cortisol secretion; the other is weak and controls the sleep-wake cycle and sleep related neuroendocrine activity. These oscillator systems may be affected by many factors such as organic diseases, drugs, and environmental factors, which may lead to psychological disorders.

Studies of seasonal patterns of incidence of psychiatric disorders have highlighted the role of seasonally regulated environmental factors on internal biological processes. Since ancient times the relationship between seasons and mood has been noted, and numerous investigations have indicated a seasonal variation in the incidence of affective illness.

Depression has been described as most common in spring and autumn, and the influence of climatological factors (mainly photoperiod) on seasonal affective disorders (SADs) have been shown. One study reported cases of SAD with summer depression and winter hypomania, and Lemoine described summer SAD (or SAD reverse) in which the temperature factor was more implicated than the daylight factor. One biological explanation has been a seasonal variation in human brain serotonin concentrations, which has been implicated in the biochemistry of affective disorders.

But if seasonal rhythms influence depressive illness, a dysregulation of circadian rhythms was found as well. There is evidence that the sleep and neuroendocrine dysfunctions observed in depressive patients are correlated with a phase advance of the circadian strong oscillator with respect to the weak oscillator. Clinical studies suggest that antidepressants can slow or delay circadian rhythms. Other therapies modifying biological rhythms may improve depressive mood. Sleep deprivation, for example, has been found to lead to rapid improvement of depressive symptomatology, and reports have shown that artificial lengthening of the photoperiod (phototherapy) may have therapeutic effects in depressive illness. The biological parameter implicated in the mechanism of action of this therapy is melatonin, for which rhythm appears to be an endocrine code of the environmental light-dark cycle conveying photic information that is used by an organism for both circadian and seasonal temporal organization.

Some authors have suggested a relationship between the season of one's birth and the occurrence of affective disorders. Season of birth/conception has also been examined as a possible factor in the depression of women who have given birth. However, although a significant seasonal variation in the occurrence of postnatal depression has been found with the largest peak occurring in autumn, there are discrepancies in the data concerning the influence of the season of conception on the frequency of postpartum mental illness.

The seasonal variation in suicides has been studied in several countries. Suicides were found to be most frequent in spring and summer in Finland and in May and September in France. Seasonal variations of other psychiatric illnesses have been less studied, although a possible link between season of birth and schizophrenia (winter and spring peaks) has been described. Biological reasons may exist, as dopamine has been implicated in the biochemistry of schizophrenia, and there is a seasonal variation in human brain dopamine concentrations.

The number of hospitalizations for alcoholism seems to peak in the spring, and there seem to be peaks in spring and summer births among alcoholics.

Human performance efficiency also has circadian rhythms in healthy individuals. One study determined that a simple manual dexterity task is almost entirely under the control of the temperature rhythm oscillator, whereas a more complex cognitive task demonstrates a periodicity that appears to be influenced by those oscillators controlling temperature and the sleep/wake cycle.

Even for human sexuality seasonal variations exist, as they do in other mammals, with a peak in autumn, probably linked to the seasonal variation of testosterone activity.

A better knowledge of all these rhythm interferences and their clinical implications brings to mind the possibility that by modifying these influences we may be able to alleviate the patient's symptoms. New approaches to the treatment of all these disorders involve direct manipulation of the biological rhythms.

BIPOLAR AFFECTIVE DISORDER (MANIC-DEPRESSIVE ILLNESS)

Clinical Description and Course

Bipolar affective disorder, formerly known as manic-depressive illness, is a psychiatric disorder involving wide-ranging fluctuations in mood, activity, and cognition. It affects between 0.8% and 1.4% of the population. When depressed, bipolar persons experience a sad mood, loss of interests, fatigue, psychomotor retardation or agitation, loss of concentration, insomnia, feelings of worthlessness, and suicidality. During manias, patients experience euphoric, elevated or irritable mood states, racing of thoughts (or the verbal concomitant, "flight of ideas"), pressure of speech, increased activity and energy, impulsive and high-risk behaviors, an inflated sense of self-worth or grandiose delusions, distractibility, and a decreased need for sleep (American Psychiatric Association, 2000). Manic episodes are generally more damaging to bipolar persons and those around them than are depressive episodes.

Bipolar I patients alternate between the two extremes of mania and depression, or they experience mania and depression simultaneously in *mixed* affective episodes. Bipolar II patients experience debilitating depressions that alternate with *hypomanic* episodes. Hypomania is an attenuated form of mania. It is not associated with significant functional impairment, psychosis, or the need for hospitalization.

Bipolar I Disorder affects men and women with equal frequency, but bipolar II patients are more frequently women. Women appear to have a preponderance of depressive episodes over manic or hypomanic episodes, whereas the reverse appears true of men. Similarly, the first onset of bipolar disorder is usually a depressive episode in a woman and a manic episode in a man.

The course of the disorder varies considerably from person to person. Some bipolar persons return to a *euthymic,* normal mood state between episodes. However, by some estimates (e.g., Harrow, Goldberg, Grossman, & Meltzer, 1990), more than half of patients have significant symptoms during the intervals between major episodes. The average duration of episodes varies from 4 to 13 months, with longer durations reported in studies from the pre-pharmacological era (Goodwin & Jamison, 1990). Episode duration has decreased significantly since the advent of mood-stabilizing agents such as lithium carbonate or the anticonvulsants (see following). But even with active medication, about 40% of bipolar patients have a recurrence of their illness in a 1-year period, and 73% over 5 years (Gitlin, Swendsen, Heller, & Hammen, 1995).

Between 13% and 20% of patients are *rapid cyclers* (Calabrese, Fatemi, Kujawa, & Woyshville, 1996), who experience four or more episodes of depression, mania, hypomania, or mixed affective disorder in a single year; these patients are disproportionately women. There are several known predictors of increased cycling of the disorder, including medication nonadherence, presence of psychosis, alcohol and drug abuse, sleep deprivation, and, in some patients, the use of antidepressant medications.

Bipolar disorder is associated with high personal, social, and economic costs. About 33% of bipolar I patients cannot maintain employment in the 6 months after a manic episode; over 50% show declines in occupational functioning over the 5 years after an episode. The suicide rate is believed to be about 30 times greater than the normal population. Bipolar disorder is also associated with marital dysfunction and high rates of divorce, general health complications, legal problems, and problems in the adjustment of children (Coryell, Andreasen, Endicott, & Keller, 1987; Coryell et al., 1993; Goldberg, Harrow, & Grossman,

1995; Dion, Tohen, Anthony, & Waternaux, 1988; Hammen, Burge, Burney, & Adrian, 1990; Silverstone & Romans-Clarkson, 1989). In 1991, the economic costs of bipolar disorder were $45 billion in the United States alone (Wyatt & Henter, 1995).

Most bipolar patients develop the illness between the ages of 19 and 23. However, prepubertal and adolescent onsets of the disorder are being increasingly recognized. In fact, the age at onset of the disorder is becoming younger in successive generations. Between 20% and 40% of bipolar patients have their first onset in childhood or adolescence, and about 20% of depressed adolescents eventually switch into mania. The early-onset form of the disease appears to have a stronger genetic liability (greater familial aggregation) than the later-onset forms. It is also frequently characterized by mixed symptoms, rapid cycling, psychosis, and other poor prognostic attributes. If bipolar teenagers are not treated early, they can fall behind, sometimes irreparably, in social, school, and work functioning (Geller & Luby, 1997; McClellan & Werry, 1997).

Etiology

Genetic and Biological Predispositions

Bipolar disorder unquestionably runs in families. Concordance rates between identical twins average 57% and between fraternal twins, 14% (Alda, 1997). The family pedigrees of bipolar probands are characterized by increased rates of bipolar disorder, unipolar disorder, and alcoholism. At least 20% of the first-degree relatives of bipolar patients have major affective disorders (Gershon, 1990). Although several gene loci have been identified, there is a particularly promising set of findings linking bipolar disorder to loci on the long arm of chromosome 18. This linkage is strongest among families of bipolar patients who are comorbid for Panic Disorder (MacKinnon et al., 1998). There is also growing evidence that a variant in the serotonin transporter gene, which might lead to instabilities in the regulation of serotonin within the CNS, may be related to the onset of bipolar disorder (Collier et al., 1996).

Bipolar disorder is presumed to involve imbalances in the activity of neurotransmitter (e.g., dopamine, serotonin) and neurohormonal (e.g., glucorticoid) systems. A recent theory of dysfunction in the activity of signal-transducing guanine nucleotide-binding proteins (G-proteins) is gaining credibility. Bipolar patients have higher platelet levels of stimulatory G-protein subunits than do normal comparison subjects, even when patients are examined in the remitted state (Mitchell et al., 1997). Lithium carbonate—the primary medication used in treating bipolar disorder—has been found to reduce G-protein function in animals (Avissar, Schreiber, Danon, & Belmaker, 1988) and in normal humans (Risby et al., 1991). Other research has focused on the protein kinase C signaling cascade, a mediator of signals within cells when receptors are stimulated by neurotransmitters. Drugs used to treat bipolar disorder, including lithium carbonate and divalproex sodium, reduce activity of the protein kinase C signaling cascade (Manji, 2001).

Psychosocial Factors

Bipolar disorder is affected by psychosocial stress. Two domains have been studied: negative affective relationships within the patient's family, and stressful life events. Regarding the former, prospective studies indicate that bipolar patients who, following an acute illness episode, return to family or marital environments that are high in "expressed emotion" (containing relatives who are highly critical, hostile, or emotionally overinvolved) are more likely to relapse at 9-month or 1-year follow-up than patients who return to low-key family environments (for a review, see Miklowitz, Wendel, & Simoneau, 1998). It is not clear whether stress within the family is a primary eliciting factor for symptoms, whether bipolar symptoms in patients evoke family conflicts, or whether patients' symptoms and family conflicts are both traceable to third variables such as a shared genetic vulnerability to mood disorder.

Episodes of bipolar disorder often follow major life events (Johnson & Roberts, 1995). Various theories have been advanced for explaining this association. One model views the core dysfunction in bipolar disorder as one of instability and postulates that mood disorders are strongly affected by changes in the circadian clock (Ehlers, Frank, & Kupfer, 1988; Ehlers, Kupfer, Frank, & Monk, 1993). Life events that affect sleep/wake rhythms and other daily routines (e.g., the birth of a baby) do appear potent in eliciting manic, but not depressive, episodes (Malkoff-Schwartz et al., 1998). Another model postulates that life events interact with a faulty "behavioral activation system" that is sensitive to reward cues. Life events that involve goal striving (e.g., a job promotion) may stimulate this system, which then produces an aroused state associated with greater motivation for rewards, heightened affect, and increased sociability or risk taking (Johnson & Roberts, 1995; Johnson et al., 2000).

A third model, the "kindling hypothesis" (Post, 1992), postulates that bipolar episodes are often precipitated by an external agent (i.e., life stress) at the beginning phases of the illness, but patients become increasingly sensitized to stress over time. In later stages of the disorder, episodes occur spontaneously, without external stressors. Eventually the illness takes on an autonomous, self-perpetuating course. Evidence for the kindling hypothesis is inconsistent. Hammen and Gitlin (1997) found that among bipolar patients who had had recurrences, those with a greater number of prior episodes were more likely to have experienced a major stressor in the 6 months prior to their recurrence, and relapsed more quickly after the stressor, than patients with fewer prior episodes.

Treatment

Biological Approaches

The primary treatments for bipolar disorder are pharmacological. Lithium carbonate was the first mood stabilizer to come into wide use. It appears to be effective for about 50–60% of patients in controlling the acute symptoms of the disorder and preventing future episodes. Anticonvulsant medications such as divalproex sodium (Depakote), carbamazepine (Tegretol), oxcarbazepine (Trileptal), and lamotrigine (Lamictal) are now used as substitutes for or in conjunction with lithium, usually for lithium-refractory patients, patients who complain of lithium's side effects, or patients with atypical presentations (e.g., mixed episodes or rapid cycling). Atypical antipsychotic agents such as olanzapine (Zyprexa) are also in use as primary, first-line agents.

Most mood stabilizers appear more effective in controlling and preventing manic symptoms than depressive symptoms. For this reason, they are often combined with antidepressants. Although often effective in controlling depressive symptoms, antidepressants pose risk to bipolar patients because they can elicit hypomanic or manic episodes or lead to an acceleration of mood cycling.

Antipsychotic agents and anxiolytic compounds are often added to patients' lithium or anticonvulsant regimes, depending upon the patients' clinical presentation. Electroconvulsive therapy (shock treatment) is recommended for treatment-refractory patients, particularly when they are in severe depressive states. Other treatment approaches that require more investigation include bright light treatment and omega-3 fatty acids (fish oil).

Medications for bipolar disorder have negative side effects. For example, lithium and divalproex sodium are associated with weight gain, nausea, and trembling. One study found that almost 60% of patients were inconsistent with their medicines in the year after their first hospitalized episode (Strakowski et al., 1998). Nonadherence is not only the result of side effects, however. Some patients miss their high, euphoric periods and dislike having their moods controlled by medication (Jamison, Gerner, & Goodwin, 1979). Some complain of a loss of creativity due to medications. Indeed, there is evidence of a linkage between bipolar disorder and artistic creativity, as evidenced by the number of writers, artists, and musicians who have had the disorder or a mild form of it (Jamison, 1993).

Psychosocial Approaches

Psychosocial therapy is used as an adjunct to drug treatment. Its purposes are to mollify the symptomatic course of the disorder, enhance patients' compliance with medications, enhance social and occupational functioning, and increase patients' ability to manage stressors that evoke symptoms. There are three treatments that have received some, albeit limited, empirical support. One is family or marital therapy, particularly psychoeducational approaches that focus on teaching patients and their family members about bipolar disorder and how to manage it and effective ways to communicate and solve family problems (Miklowitz & Goldstein, 1997; Miklowitz et al., 2000). A second is interpersonal and social rhythm therapy, an individual therapy that focuses on helping the patient understand and renegotiate the interpersonal context associated with mood disorder symptoms (Frank, Swartz, & Kupfer, 2000). Patients learn to stabilize sleep/wake rhythms and other daily routines, particularly in the face of environmental triggers for disruption. A third treatment is individual cognitive-behavioral therapy, in which patients learn to identify, evaluate, and restructure cognitive distortions, and develop illness management strategies such as behavioral activation, drug compliance monitoring, and the appropriate use of support systems (Cochran, 1984; Lam et al., in press; Otto, Reilly-Harrington, & Sachs, in press).

Conclusion

Bipolar disorder is a genetically- and biologically-based illness of mood states. It takes a tremendous economic, social, and personal toll on sufferers and their family members. Recent advances in biological psychiatry and psychosocial research have clarified some of the predisposing factors for the disorder and have identified triggers for the disorder's cycling. Advances in its pharmacological and psychological management are being translated into treatment algorithms that have the potential to improve community-based care for this often debilitating disorder.

BIRTH ORDER

Birth order refers to the ordinal sequence of birth for each child in the family. Some researchers identify five positions: (only, first, second, middle, and last), while others use four positions (only, first, middle, and last). Alfred Adler was the first theorist in modern psychology to note the significance of psychological birth order position in the dynamics of personality development. Adler recognized that the addition of each child to the family would have a profound effect on the family system, noting that the birth of each child would alter the interactions, roles, and responsibilities of each family member.

Although birth order is important, Adler suggested, the "psychological order" of the child might be more important than the ordinal position. The psychological birth order position is a vantage point from which a child perceives and evaluates itself and forms convictions about what is required to belong to society. The term *family constellation* is used to describe the family environment—the parents, siblings, and others living in the family of origin.

Variables

A number of family variables influence the child's perception of the birth order and create a different psychological order from the ordinal position. These variables influence how the child will evaluate the birth order position and decide whether that birth order is the best or the worst position in the family; for example, a first born may evaluate the heavy responsibilities expected of the oldest child and decide that it is easier to be lazy than assume leadership. A middle child may see that the leadership demonstrated by the oldest child is inferior and decide to leapfrog into a role as the leader of the group. Each child will evaluate his or her birth-order position in relation to the other siblings and decide on a pattern of behavior to enable that child to become unique in the family structure.

Corsini and Manaster (1982) maintain that the important factor relative to birth order and personality development is the child's perception of the role to be played and its demands and expectations. Age spacing and the other variables subsequently listed may influence such perceptions, but in the final analysis, the child is responsible for these perceptions.

In the study of birth order, the sex of the child is an important variable because each child searches to establish his or her sex-role identity by finding a role model in the family. Parents have different sex-role expectations for each child and reinforce or reward the child's behaviors in accordance with their expectations.

The structure of the family is important to consider when examining the various influences on the child. The family structure includes a description of the sex of each child and the sequence of birth of each child. A family of four children could have a birth order and sequence combination to form sixteen different family structures. A family of four boys (boy, boy, boy, boy) is very different from a family of four girls (girl, girl, girl, girl). Another family of four children (girl, boy, girl, boy) is quite different from another family of four children (girl, girl, boy, boy). The sequence of birth and the gender of each child will influence how siblings are likely to group and interact.

The age separation between siblings is another important consideration in the development of personality. Closely spaced children have a strong influence on each other because they are likely to play together extensively. Children who are born several years apart have less influence on each other than those who are closely spaced. Two or more families can exist within the family unit; when children are born (at least) five years apart, the family can be considered to have a second generation of children within the same family unit.

Parents hold different expectations for each child based on the sex, age, and size of the child. A first-born daughter is often required to assume responsibilities and act as the "Junior Mom" by supervising the younger siblings. Similarly, a first-born son is often expected to be the "Junior Dad" to the younger siblings. A last-born child is recognized as the "baby" and may utilize learned helplessness to keep other people busy with his or her problems. Parents may pamper their youngest child and give it many privileges that the older siblings did not receive.

Parents may choose a favorite child based on their own birth order. A last-born parent may identify with the last-born child and say, "I know what that child is going through; I know what it feels like to be picked on by those older kids." When one parent and a child establish a strong bond, the remaining children will seek other role models.

How parents interact with the child is often influenced by the age of the parents. Teenage parents are very energetic and are likely to play with the child, whereas parents in their late 30s are more likely to be academic and will read to the child. Mature parents provide their first-born child a different socioeconomic environment than teenage parents.

A family with multiple births (twins, triplets, quadruplets, and quintuplets) will have special circumstances because of their shared environment. Multiple-birth siblings often bond closely and develop private language or symbols for communication. Identical twins experience similar family environments and develop common traits, yet they find subtle ways to differentiate themselves.

A child who requires special care, for example, a child with a disability, will alter the expectations for each member of the family. Each family member will have some role in the care of this child.

Any conditions that may lead the parents to give special consideration or protection to a child may have an influence on the family environment. A parent who has several miscarriages before the successful birth of a child may become an overprotective parent. The death of a sibling during

childhood will have a profound effect on each of the surviving family members.

BISEXUALITY

Bisexuality is a word applied to an adult whose desire for, and/or choice of, sexual partners includes persons of both the opposite and the same sex. In conception, the bisexual person should have no preference, being equally attracted to both males and females, but the term is often misapplied to individuals who have partners of both sexes and also have a clear preference for one or the other sex.

The prototype bisexual is the "3" on the 7-point scale of sexual preference proposed by Alfred Kinsey and his associates in their classic book, *Sexual Behavior in the Human Male.*

While individuals who have sexual contact with persons of both sexes are not uncommon, true bisexuals are relatively rare. Kinsey and his colleagues found that just more than 3% of adult White males fit his definition of *bisexual.* Among females, a little more than 1% of the single females were 3s.

BLOOD-BRAIN BARRIER

The blood-brain barrier (BBB) is the interface between blood and brain and, therefore, plays an important role in many disciplines, including psychology, psychiatry, nutrition, general metabolism, as well as pharmacology, neurology, and neurosurgery (Pardridge, 2001). The BBB evolved in parallel with myelination of the brain, is present in the brain of all vertebrates, and is formed within the first trimester of human fetal life. The anatomical localization of the BBB is the capillary endothelium of brain. Unlike capillary endothelial cells in peripheral tissues, the endothelial cells of capillaries perfusing the brain and spinal cord are joined together by epithelial-like, high-resistance tight junctions that eliminate the normal paracellular pathway of solute flux from blood to the organ interstitium (Brightman, Reese, & Feder, 1970). There is also a 99% reduction in the pinocytosis in endothelia of the central nervous system (CNS), and this eliminates the normal transcellular pathway of free solute exchange between blood and the organ interstitial space.

The paracellular and transcellular pathways for free solute exchange across the capillary wall that are present in the microcirculation of peripheral organs are absent in the capillaries perfusing the brain and spinal cord. Therefore, circulating molecules gain access to brain or spinal cord by only one of two processes: (1) free diffusion based on the lipid solubility and molecular weight of the molecule, and (2) catalyzed transport (Oldendorf, 1974). The latter involves either carrier-mediated transport (CMT) for small molecular weight nutrients such as glucose or amino acids, or receptor-mediated transcytosis (RMT) for certain circulating peptides such as insulin, leptin, or transferrin (Pardridge, 2001). The CMT and RMT systems are individual proteins expressed by specific genes within the capillary endothelium. The CMT and RMT systems mediate the transport of nutrients or some endogenous peptides across both the luminal plasma membrane of the capillary endothelium, at the blood surface, and the abluminal membrane of the capillary endothelium, at the side of the brain interstitial fluid. The luminal and abluminal membranes are separated by approximately 300 nm of endothelial cytoplasm. Therefore, transport across the BBB is a process of molecular transfer through two membranes in series: the capillary endothelial luminal and abluminal plasma membranes. If a molecule does not have access to one of the specialized CMT or RMT systems within the BBB membranes, then there is no significant uptake of the molecule by brain.

The capillaries within the brain are approximately 40 microns apart, and it takes a small molecule such as glucose to diffuse 40 microns around 1 second. The capillary transit time in brain is approximately 1 second. Therefore, the angioarchitecture of brain has evolved to allow for instantaneous solute equilibration throughout the brain interstitium once the molecule crosses the limiting membrane, which is the BBB. The endothelial cell shares a capillary basement membrane with the pericyte, which sits on the abluminal side of the endothelium. The pericyte has an antigen presentation role in the CNS (Pardridge, 2001). More than 99% of the brain surface of the capillary basement membrane is invested by astrocyte foot processes, and the distance between the astrocyte foot process and the capillary endothelium is only 20 nm or 200 angstroms, and this distance is equal to the thickness of the capillary basement membrane. There are no tight junctions between astrocyte foot processes, and the astrocyte foot process constitutes no permeability barrier in brain. While the permeability of the

BBB is strictly regulated by the endothelial cell, the total function of the brain microvasculature is determined by the paracrine interactions between the endothelial cell, the pericyte, the astrocyte foot process, and the occasional nerve ending that terminates directly on the brain side of the capillary.

CNS Drug Development

Molecules that are lipid soluble and have a molecular weight under a 500 Dalton threshold are able to cross the BBB in pharmacologically significant amounts (Pardridge, 2001). All present-day CNS drugs in clinical practice fulfill these dual criteria of (1) lipid solubility and (2) molecular weight under a 500 Dalton threshold. If a molecule lacks both of these criteria, it is unlikely that the molecule will cross the BBB in pharmacologically significant amounts, unless the molecule has affinity for one of the CMT or RMT systems in the BBB. In the absence of this, the molecule will need a brain drug delivery system if the drug is to be used as a neuropharmaceutical. Since more than 98% of the drugs that emanate from high throughput receptor-based CNS drug discovery programs will not cross the BBB, the presence of the BBB poses a significant problem for future CNS drug development. On this basis, it is important that there be parallel progress in both CNS drug discovery *and* CNS drug delivery so that these two pathways can be merged in the overall CNS drug development process. Unfortunately, less than 1% of present-day CNS drug development is devoted to CNS drug delivery, and more than 99% is applied to CNS drug discovery.

Blood-Brain Barrier Function in Psychologic Stress

Blood-brain barrier disruption occurs in pathologic states such as the recovery from stroke, infection of the brain, or brain tumors. In addition, there is evidence that the BBB is disrupted in states of severe stress or emotionality. This phenomenon may occur in patients who are acutely admitted to a hospital under severe stress. In this setting of transitory BBB disruption, drugs that are normally excluded from the brain may cross the disrupted BBB. This process may underlie the high incidence of CNS neurotoxicity in acutely hospitalized patients. The biochemical basis of BBB disruption is poorly understood and is an area in need of additional research. Once the biochemical basis of this process is elucidated, new drugs may be developed to prevent BBB disruption in states of severe emotionality.

BOGARDUS SOCIAL DISTANCE SCALE

The Bogardus Social Distance Scale was one of the first techniques for measuring attitudes toward racial and ethnic groups. The basic concept behind the Bogardus scale is that the more prejudiced an individual is against a particular group, the less that person will wish to interact with members of that group (R. M. Dawes, 1972). Thus, the items that compose a Bogardus scale describe relationships into which a respondent might be willing to enter with a member of the specified cultural group (e.g., spouse, friend, neighbor, coworker, citizen, visitor to our country, etc.). Items are worded in terms of either inclusion or exclusion. “Would you accept an *X* as a spouse?” is an example of an inclusion-type question. “Would you keep all *Y*s out of America?” is an example of an exclusion-type question. The attitude or esteem with which the respondent holds the specified group is defined as the closeness of relationship that the respondent reports as being willing to accept with a member of that group.

In E. S. Bogardus’s (1928) early work, he found that White Americans maintained relatively small social distances from groups such as the British, Canadians, and northern Europeans, but greater social distances from southern Europeans. Groups that differed racially (e.g., Blacks and Orientals) were subject to even larger social distances. Extending the typical use of Bogardus scales, H. C. Triandis and L. M. Triandis (1960) used multifactor experimental designs to separate the independent effects of varying aspects of group membership (e.g., race, religion, and occupation). Triandis and Triandis (1962) later showed that various aspects of group membership of the respondents interact with the social distances they assign various other groups. Thus, Americans were found to consider race an important variable, whereas Greeks considered religion to be more critical. Personality factors such as dogmatism have also been shown to be related to one’s proclivity to desire relatively large social distances from groups other than one’s own.

The Bogardus scale is a type of Guttman scale. Thus, someone willing to accept members of a certain group as friends would also be willing to accept them as neighbors, coworkers, fellow citizens, and all other more distant rela-

tionships. While the responses of some individuals do occasionally reverse the rank-ordered nature of the items, average responses of groups (e.g., cultural or racial groups) tend to maintain the order in a well-constructed Bogardus scale (H. C. Triandis & L. M. Triandis, 1965). Hence, the Bogardus approach to attitude measurement is an effective means of estimating the esteem with which a group of individuals is held by other distinct groups of people.

Although the Bogardus approach to measuring attitudes between and among groups is primarily of historical importance, it continues to be used in recent years. It has generally been employed to assess attitudes in the sense of social distances among both ethnic and racial groups (e.g., Adler, 1985; Kleg & Yamamoto, 1998; Kunz & Yaw, 1989; Law & Lane, 1987), as has been the case historically, and among various psychologically defined groups (Maddux, Scheiber, & Bass, 1982) and groups representing those with various disabilities (Eisenman, 1986; Tolor & Geller, 1987).

BONDING AND ATTACHMENT

John Bowlby introduced the term *attachment,* which was established as the essential concept for a new theoretical approach that combines ethology and psychoanalysis for understanding the origins of a child's bond to the mother.

Ethological Theory and Attachment

Animal studies suggest that lasting attachments are formed by a process of *imprinting* that occurs in a short time span at an early critical period of life. Ethology assumes that genetically preprogrammed behaviors important for species survival interact with the environment to produce bonding.

Konrad Lorenz, a pioneer in the study of imprinting, demonstrated that newly hatched fowl such as goslings would become fixed upon and follow the first moving proximal object or person they encountered shortly after birth. Niko Tinbergen demonstrated that the fight-flight response in animals evolves into socialized ritualistic behaviors. Robert Zaslow concluded from studies of the pathology of attachment found in infantile autism that the formation of attachment depends on two bonding networks of behavior: (1) the body–contact bond, necessary for intimacy and basic trust; and (2) the eye–face–contact bond, necessary for integration, focus, and direction of behavior.

Learning Theory and Attachment

Learning theorists have stressed the importance of feeding as a primary drive-reducing reinforcement mechanism for the development of attachment to the mother as a learned process. The satisfaction of the primary drive of hunger results in a positive attachment to the mother through a secondary reinforcement in the feeding situation. A new development in learning theory appeared when Harry Harlow stated that oral gratification through feeding was not sufficient to develop attachment and affection when mannequin monkey mothers were used.

Development of Attachment

In general, attachment emerges in a series of developmental steps that are species-specific. In the beginning, the infant is attached to all humans who exhibit species behaviors that are effectively compatible. Bowlby describes the development of attachment behavior as having four phases: (1) orientation and signals as a general reaction with no discrimination of a specific person, (2) orientation and signals directed to one or more discriminated people, (3) maintenance of proximity to a person by means of locomotion and signals, and (4) formation of a reciprocal relationship with people. Strong attachments to specific persons appear at approximately 7 months of age and are exhibited as a fear

of strangers. Infants display protest behavior in the form of anger and resistance when separated from a person to whom they are attached. The protest behavior is increased in an unfamiliar environment, indicating attachment to place as well as to people. As cognition and memory develop in the child, the intensity of protest and the need for physical proximity are reduced because the separation is seen as temporary.

Quality of Attachment

The stability and strength of attachment depends on the quality of parental–infant interaction patterns. A positive attachment is developed by a combination of nurturant-affectionate behaviors and the expression of resistant-angry behaviors in the infant and child. Chronic unresolved anger in parent and child disturbs attachment formation. Rhythm and timing have been found to affect the quality of attachment. Infants are more attached to the parent who responds quickly and spontaneously initiates interactions. Later studies by Ainsworth reveal that the quality of attachment depends on stimulation and control of the environment and child. Ainsworth stated that infants may be securely or anxiously attached, thus affecting the quality and stability of attachment.

Attachment and Psychopathology

Bowlby showed that after the initial positive bond is formed between mother and infant at about 6 months, the infant reacts to loss of the mother in three characteristic stages. First, there is *protest*—crying and anger that serve to bring mother back. If this is unsuccessful, a period of *despair* follows, characterized by withdrawal, depression, and decrease in activity. Finally, a stage of *detachment* appears in which the infant is relatively unresponsive to people. The child's anger toward the mother figure is a central feature of this pattern. The anger is expressed openly in the protest phase and indirectly in the detachment phase. Bowlby stated that the separation experience elicits intense and violent hatred of the mother figure.

Bowlby's observations on separation and loss are supported by the infant studies of Ainsworth and a number of infrahuman primate studies. René Spitz described anaclitic depression as a condition in which the infant, when separated from the mother, dies because of hospitalization. Zaslow and Breger made an attachment analysis of early infantile autism that is followed by separation and loss. They derived several theoretical conclusions applicable to normal human attachment and the psychopathology of attachment. The first was that holding a child in a state of protest behavior, characteristic of infant-child crying, forms a stress-to-relaxation cycle that is a fundamental unit of positive attachment. The greater the intensity of protest, the greater the relaxation and the stronger the bond between child and parent. The second conclusion was that social-affective human attachment is to the face and not to the breast. The human species-specific behaviors important for the maintenance of face-to-face interactions, such as smiling, crying with tears, talking, and listening, are not found in the autistic child, who strongly resists eye-face contact. These provide an alternative behavioral network to the fight-flight response that results from the stress of prolonged eye-face contact found in lower species.

Bowlby reached a general conclusion about attachment theory and its relationship to psychopathology with the view that attachment theory is a scientifically valid system that incorporates concepts derived from psychoanalysis, ethology, cognitive theory, and control theory.

BOREDOM AND BOREDOM PRONENESS

Boredom is an emotional state ranging from mild to severe discontent that people describe as a feeling of tedium, monotony, ennui, apathy, meaninglessness, emptiness, lack of interest, and disconnection with the current environment. Boredom is the state—the current condition. Boredom proneness is the trait—a tendency to experience tedium and little personal involvement and enthusiasm, a general or frequent lack of sufficient interest in one's life surroundings and future. The most commonly used measure of boredom and boredom proneness, as with many internal emotional conditions, such as depression and anxiety, is some form of self-report. Behavioral indicators could include yawning, "glazed" eyes, slumped posture, restlessness, and such signs of inattention as looking around the room. Emotions or states opposite to boredom include interest, enthusiasm, involvement, engagement, and optimal stimulation.

Paradoxically, boredom is interesting for both practical and theoretical reasons. Boredom is of practical importance because of its relation to many social problems, such as delinquency, dropping out of school, drug abuse, low morale, poor industrial production, job turnover, and problems of living in institutions such as prisons, mental hospitals, military settings, and nursing homes. Being boring is a condition that all lecturers, entertainers, and advertisers try to avoid. Although boredom is an emotion that probably everyone has experienced, it has received much less research attention than emotions such as depression and anger. One review, covering 1926 to 1980, found less than one article per year on boredom. However, between 1992 and 2002, the pace of research and theoretical activity had increased, and PsycINFO citations occurred at the rate of ten per year.

In addition to practical reasons, there are important theoretical reasons to understand boredom as a motivational concept connecting inner feelings and motives with environmental conditions. Theories relate boredom to attention, arousal, information processing, and stimulus underload. In 1960 Berlyne (1960, p. 187) stated that boredom is "a drive that is reduced through divertive exploration and aroused when external stimuli are excessively scarce or excessively monotonous." The most common theoretical approach construes boredom as occurring in situations with less than the optimal level of stimulation. Theorists tend to emphasize either external conditions or internal predispositions or characteristics. Industrial research is mainly concerned with external conditions as they affect productivity. Among others, Zuckerman emphasized internal elements and saw boredom susceptibility as a part of a stimulus-seeking model. For existentialists, a distinction may be made between existential boredom (the sense of lack of intrinsic meaning in life) and neurotic boredom (an anxious lack of interest or purpose). Some psychoanalytic thought brings another possible research-generating element—sense of control. In 1951 Fenichel stated that boredom occurs "when we must not do what we want to do, or must do what we do not want to do." (Fenichel 1959, p. 359).

Boredom involves ongoing person-environment relationships—the fit of the individual's characteristics to the situation's characteristics. Csikszentmihalyi explored the balance of boredom with anxiety, both being mismatches between environmental challenge and personal competence. Boredom occurs in situations in which a person's capabilities are greater than situational opportunities for expression, whereas anxiety comes when the environment demands more of the person that he or she is able to perform at the time. The achievement of balance occurs in "flow," a condition of pleasurable absorption in an activity. Cross-cultural issues, such as collectivism versus individualism, offer additional theoretical challenges for exploring boredom as an important relation between persons and social environments.

Research on boredom mainly falls into two general categories: (1) experiments in which conditions are manipulated using a stimulus situation assumed to be boring, such as vigilance tasks (e.g., watching radar screens for long periods) or other monotonous tasks (e.g., crossing out a given letter on pages of random letters); and (2) correlation of ratings or questionnaires about boredom with other measures or conditions. A few tests have been developed. Zuckerman's Stimulus Seeking Scale included a Boredom Susceptibility subscale. Another is the Boredom Proneness Scale, or BPS, by Farmer and Sundberg, a 28-item self-report scale that shows good reliability and some evidence of validity but does not correlate significantly with the Zuckerman subscale. Vodanovich and Kass identified five factors in the BPS conceptually very similar to those discussed in the literature: external stimulation, internal stimulation, affective responses to boredom, perception of time (slowness), and constraints (on self-initiated actions). In several studies males are more boredom prone than females. Boredom may be highest in adolescence and may decrease with age. The BPS relates to disinclination to vote, narcissism, forms of self-absorption, and pathological gambling. Several studies have shown a moderate overlap between boredom and negative emotions, such as depression and loneliness.

Physiological factors in relation to boredom have been explored. Zuckerman advocated a physiological basis for boredom and sensation seeking in line with Eysenck's theory. Eysenck postulated that the arousal systems of extroverted people require more stimulation than those of introverts; therefore, in seeking optimal levels of stimulation, extroverts are more outgoing, carefree, and impulsive. In a 1981 review, Smith noted that the most consistent finding was that extroverts were especially vulnerable to boredom. Others reviewing the biological evidence related to monotony avoidance and impulsiveness (which are aspects of extroversion) concluded that there is an association between certain neurochemical activities (especially that of monoamine oxidase, or MAO) and impulsiveness and sensation seeking. Hamilton found increases in capacity for sustained attention in relation to biological indicators during development in later childhood and adolescence.

Coping with boredom is another area of study. Hamilton developed a brief self-report measure of intrinsic enjoyment and boredom coping. She and her colleagues have found these measures to be related to ability to attend to a performance task for long periods—an important element in many industrial and military situations. Fantasy is one way of coping with monotonous situations, and a paucity of fantasy may be related to boredom proneness. Addictive behaviors may be used in coping with boredom, including overeating. Reported boredom is related to school performance. Boredom also appears to be a signal of problems with creativity. Clinicians have been concerned about coping with boredom during psychotherapy either on the part of the patient or the therapist, seeing it as an indicator of problems in transference or countertransference. The positive function of boredom may be to alert a person to do something different.

In conclusion, boredom seems to be generating more and more research attention. At this point, the findings suggest hypotheses for many kinds of studies. There is a strong need for further theoretical development integrating the empirical results with a larger theory of emotions.

BRAIN

The human brain is a complex aggregate of billions of cells working together to process stimuli, to monitor needs, and to direct behavior. Developmentally, the brain begins at the most rostral extension of the neural tube; it bends over and convolutes as it expands within the confines of the skull (cranium). The brain's expansion is disproportionate relative to the growth of the spinal cord, the most caudal extension of the central nervous system. Figure 1 illustrates the development of the human brain, showing its major subdivisions.

There are three major sections of the brain: the *prosencephalon* or forebrain, the *mesencephalon* or midbrain, and the *rhombencephalon* or hindbrain. The forebrain is the largest and most expansive and is made up of two subdivisions: the telencephalon (endbrain) and the diencephalon (interbrain). Telencephalic structures account for about 75% of the weight of the entire human central nervous system. These structures include the two cerebral hemispheres that are connected by a mass of crossing fiber tracts (the corpus callosum). The surface of the hemispheres is a multicellular layer of brain tissue about 4.5 centimeters thick, called the *cerebral cortex.* The cortex is divided into subregions according to gross anatomical landmarks called *sulci* and *gyri.* The largest subregions are called *lobes,* of which there are four in each hemisphere: frontal, parietal, temporal, and occipital. The location of the four lobes and other major brain structures can be seen in Figures 1 and 2. The occipital lobes have visual functions. The temporal lobes are important for audition, learning and memory, and, on the left side of the brain, for understanding language. The parietal lobes control visuospatial and somatosensory functions, and at the junction with the temporal lobe, the left parietal cortex is important for language comprehension. Frontal cortex is polysensory; it is known to be important in movement, impulse control, emotional behavior, problem solving, and, on the left side, language expression.

In the cerebral hemispheres the cortex has a laminar architecture with the different neuronal cell types organized in layers. From an evolutionary standpoint, the layered cor-

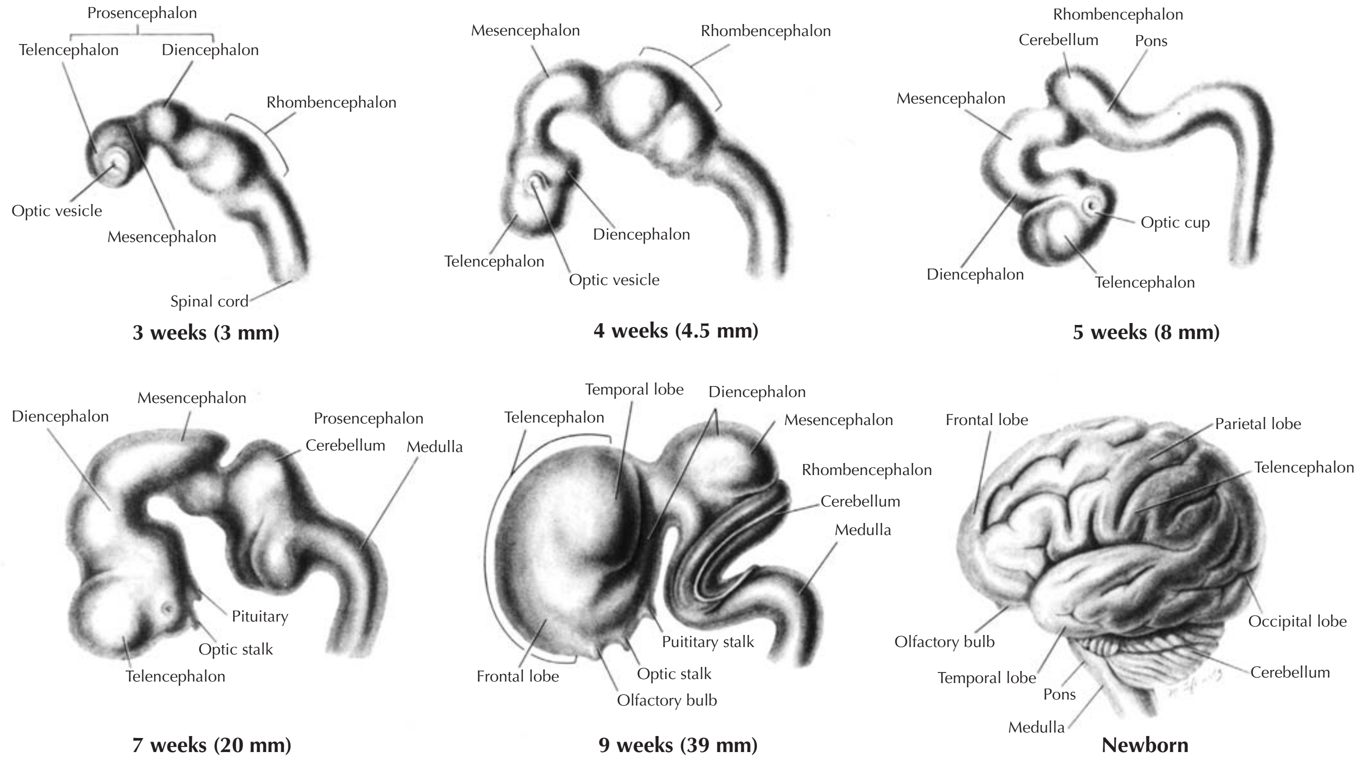

Figure 1. The development of the human brain, showing its major subdivisions.

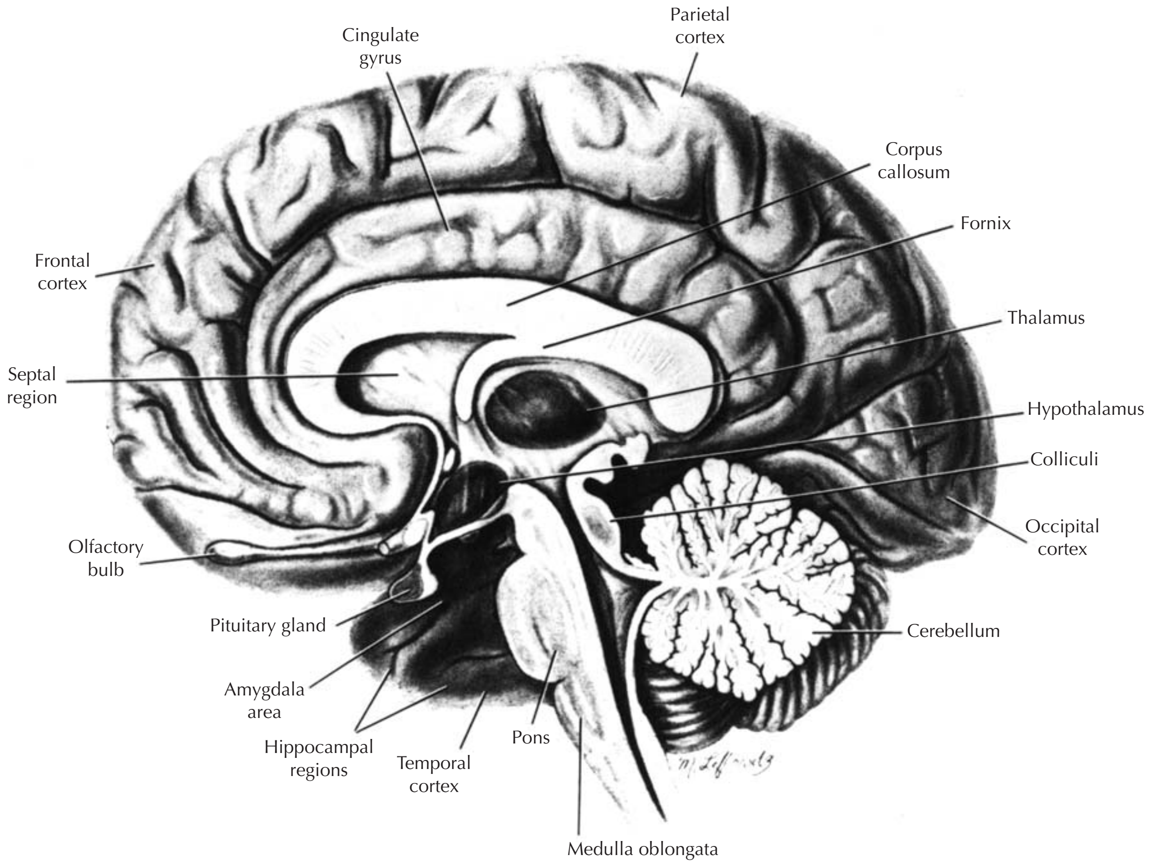

Figure 2. The location of the four lobes and other major brain structures of the adult brain.

tical areas have changed in complexity across the phylogenetic scale. Cortical nerve cell bodies collectively appear gray, thus accounting for the fact that cerebral cortex is commonly called *gray matter.* Likewise, nerve fibers emanating from the cell bodies, because of their collective white appearance subcortically, have been referred to as *white matter.* These fibers connect with other nerve cells that are aggregated in clusters called *subcortical nuclei.* In the telencephalon, the subcortical nuclei include the septum, the amygdaloid complex, and nuclei of the basal ganglia (caudate, putamen, and globus pallidus). Septal and amygdala regions are intimately connected to each other and are important in emotional and motivational functions. The basal ganglia are concerned largely with various aspects of motor control.

The cerebral hemispheres are attached to the diencephalon by massive fiber bundles, the corona radiata. Major structural components present in the diencephalon include the thalamus (a way station for incoming neurons); the subthalamus (a way station between the thalamus and the cortex); the hypothalamus (literally, "under the thalamus"); and the epithalamus (containing the pineal body and the habenular complex).

The middle section of the developing brain is called the *mesencephalon* or midbrain. At maturity the mesencephalon resembles its early embryonic form more closely than do either the prosencephalon or the rhombencephalon. The mesencephalon is made up of three main parts, the tectum (containing auditory and visual relay stations called the *inferior and superior colliculi*), the tegmentum (containing the midbrain reticular formation that activates attention, the substantia nigra that subserves motor functions, and numerous other nuclear groups), and the crus cerebri (a descending bundle of fibers).

The third major section of the brain, part of which eventually exits into the spinal cord at the base of the skull, is the rhombencephalon or hindbrain. It is composed of two subparts, the metencephalon (consisting of the pons and cerebellum) and the myelencephalon (the medulla oblongata). The cerebellum is a prominent eminence; it is the center for motor skills and also subserves certain types of learned activities. The pons and medulla oblongata contain clusters of cranial nerve nuclei that connect the nerves going to and from the face and head. Because of the shape and position of the pons and medulla at the base of the brain, they often are referred to as the *brain stem,* although this term usually includes structures in the midbrain and lower diencephalon as well.

The various components of the brain are interconnected through a very complicated network of neuronal pathways, and neurons are in continuous communication (through specialized chemicals called neurotransmitters). Nuclei

within the brain seldom act autonomously. Instead, several nuclei and their fiber tracts may act together to organize and modulate complex behaviors. The functions subserved by these many diverse structures and systems are generally similar in all normal, healthy adults. Sensory systems regulate information coming from outside and inside the body; attentional systems not only keep us alert, but also allow us to ignore stimulus information that may be irrelevant and to rest when we need to; motor systems regulate how we respond and move about; and emotional and motivational systems monitor drives and needs and homeostasis. Other systems help us to learn and to remember or forget. Together, the functioning brain is essential to every aspect of life and consciousness.

BRAIN-DERIVED NEUROTROPHIC FACTOR

Brain-derived neurotrophic factor (BDNF) is one of a series of peptide growth factors secreted from neurons and having its own specific receptor. Nerve growth factor (NGF) has TRKA as its receptor, BDNF has TRKB, and neurotrophic factor 3 (NT-3) acts at the TRKC receptor. These neurotrophic factors appear to have different functions at different stages of neurogenesis and development.

It appears that they are crucial for the initial neuronal and synaptic connectivity of the central nervous system (CNS), during which cells that "fire together, wire together." At this stage of development, many of the neurotrophic factors are secreted by the cell bodies of the stimulated (postsynaptic) neurons, picked up by axon terminals, and retrogradely transported back to the nucleus of the innervating neuron; in this manner they alter the patterns of gene expression for maintenance of synaptic efficacy and even neuronal survival. In addition to a role in the basic wiring diagram of the CNS, it would appear that they are also involved in a more subtle sculpting and resculpting of the CNS based on experience-dependent neural plasticity.

In the adult animal, BDNF appears to be integrally involved in long-term potentiation and other models of learning and memory. For example, in genetically modified mice in which BDNF is knocked out, long-term potentiation fails. This failure appears to be physiologically and functionally relevant to the animal because it is unable to navigate based on spatial cues to find a previously discovered submerged platform in the Morris water maze test.

Although it has not been definitively demonstrated, considerable new evidence suggests that BDNF and related neurotrophic factors may be released in a feed-forward fashion with neuronal firing, rather than simply having uptake and retrograde transfer back to the innervating neuron. This is potentially of considerable interest in the dentate granule cells of the hippocampus, which not only are involved in the trisynaptic glutamate-based excitatory circuitry important for learning and memory, but also are capable of producing (and likely releasing) BDNF from their presynaptic terminals.

In the amygdala kindling paradigm wherein repeated subthreshold stimulations of the amygdala eventually come to evoke full-blown tonic-clonic seizures, the dentate granule cells show dendritic sprouting as well as axonal sprouting onto the CA3 pyramidal cells. While kindling induces increases in BDNF mRNA expression, stresses decrease in the same area of the dentate granule cells of the hippocampus.

There is some specificity of the effects on BDNF as a function of both anatomical area involved and specific type of neurotrophic factor. Thus, although stress decreases BDNF in the hippocampus, it increases NT-3, and the effects on BDNF are in the opposite direction in the hypothalamic-pituitary-adrenal axis, which hypothetically could contribute to the increased size of the pituitary and adrenal glands in patients with major depression.

In neonatal rat pups, 24 hours of maternal deprivation results in substantial decrements in BDNF in the hippocampus and a doubling in the rate of the diffuse neuronal apoptosis that occurs in the 12-day-old animal. Repeated experiences of maternal deprivation for 3 hours in the first 10 days of life result in an animal that is permanently hyperactive and hypercortisolemic, as well as prone to alcohol and cocaine self-administration as compared with its non-deprived litter mates. These biochemical and behavioral defects are reversed by chronic treatment with serotonin-selective antidepressants but return when these treatments are discontinued. While alterations in BDNF or other neurotrophic factors have not been definitively linked to these long-term biochemical and behavioral changes in this psychosocial stressor paradigm, they provide a plausible mechanism.

The potential bidirectionality of such experiential effects is further emphasized by the work of Meaney and colleagues, who observed that 15 minutes of maternal deprivation resulted in increased maternal attention and licking upon reunion and subsequently thereafter, and thus engendered protective effects against stress-related hypercortisolemia and even age-related decline in hippocampal structure and memory loss. Parallel effects were observed in the offspring of mothers who were high natural lickers of their infants compared with those who naturally engaged in lesser degrees of this grooming and contact behavior.

Many of the currently utilized psychotropic agents have effects on neurotrophic factor gene expression, including that of BDNF. Smith and colleagues were the first to demonstrate the opposite effects of stress and antidepressants on BDNF mRNA in the hippocampus; these data were replicated and extended by Duman and colleagues at Yale.

They found that antidepressants as a class, including electroconvulsive therapy, increase BDNF gene expression following chronic administration. Moreover, there is partial amelioration of some of the stress-induced decrements in BDNF gene expression if antidepressants are used prior to or concurrently with the stress induction.

From the clinical perspective, this raises the potential of different types of benefit from long-term antidepressant prophylaxis in individuals with recurrent unipolar depression. They prevent recurrent depression, and to the extent that the preclinical data in animals are relevant to the human condition—and some preliminary autopsy data from the Stanley Foundation brain collection are at least consistent with this perspective—it is possible that antidepressants could be partially protective to the effects of stressors on BDNF gene expression. This might be useful and neuroprotective in its own right, but to the extent that some types of stressors are involved in the triggering of affective episodes, this could be involved in depression prophylaxis.

Preliminary evidence also suggests that BDNF is positive in some animal paradigms predictive of the efficacy of antidepressants, further raising the speculation that more direct targeting of BDNF specifically for therapeutic purposes, either by increasing BDNF itself or increasing activity at its TRKB receptor, may ultimately provide a new approach to the therapeutics of depression, possibly at a level of primary as well as secondary prevention.

BRAIN EVOLUTION

Most neurons have long processes that allow rapid cell-to-cell communication over long distances within an organism. The evolutionary gain of neurons allowed an explosive new radiation of multicellular animals, most of which have bilateral symmetry and a centralized nervous system. The rostral part of centralized nervous systems is composed either of a localized collection of ganglia or a unitary brain; the term *brain* will be used here loosely to refer to both conditions.

Brain Elaboration: A Repeating Theme

Brain evolution is a story of brain diversity. Brains have independently evolved multiple times in the many separate lines of invertebrate and vertebrate groups. In some groups, brains are simply organized, and many species with relatively simple brain organization have been evolutionarily successful. In many other instances, brains have become enlarged and elaborated with more distinct neuronal cell groups (nuclei), more extensive interconnections of these cell groups, lamination of the neurons and fiber (axonal) systems in some regions, and a greater variety of neuronal cell types.

Among invertebrates, brain enlargement and elaboration have occurred independently multiple times (Breidbach & Kutsch, 1995)—within molluscs such as *Nautilus,* squid, and octopus and within arthropods such as insects. Among jawed vertebrates, brain enlargement and elaboration have occurred independently for some members within each major group—cartilaginous fishes, ray-finned (including bony) fishes, and tetrapods. Often, anatomical complexity appears to be correlated with behavioral complexity.

Seminal Events in Vertebrate History

In the line leading to vertebrates, several major evolutionary events occurred that established the basis for most

parts of our nervous systems, including major gains in sensory system structure and the motor neuron–musculature system (Butler & Hodos, 1996; Nieuwenhuys, ten Donkelaar, & Nicholson, 1998). The brain and spinal cord were greatly enlarged, and the vertebrate sensory systems—including olfactory, visual, somatosensory, auditory, vestibular, gustatory, and lateral line (mechanosensory and electrosensory)—were gained (Northcutt, 1996). Motor neuronal pools for the muscles of the face and throat (pharynx) regions and, subsequently, for eye muscles and then jaw and neck muscles were gained. In the ancestral line leading to tetrapods, sets of paired appendages and a muscular tongue were gained along with their respective motor nuclei, while the lateral line system was lost.

Brain Evolution in Vertebrates

In those groups with enlarged and elaborated brains, the more dorsal (alar plate–derived) parts of the brain tend to show more variation than the more ventral (basal plate–derived) parts. Structural elaboration is often correlated with a major exploitation of a particular sensory aspect of the world or with the gain of complex behaviors (see Butler & Hodos, 1996, and references therein). For example, mormyrid fishes utilize an expanded cerebellum and lateral line lobe, which are alar plate–derived, in their complex electrosensory communication system for individual recognition, nest building, and care of their young. Many tropical reef fish have greatly enlarged forebrains and complex territorial, courtship, and parental behaviors. Some cartilaginous fishes also have substantially enlarged forebrains used in complex sensory processing.

Within the brain stem across amniotes (reptiles, birds, and mammals), similarities exist for many of the nuclei, but the alar plate–derived, sensory part of the trigeminal nerve is very versatile. It generally supplies touch, position sense, pain, and temperature for the face but also innervates mechanosensory and electrosensory receptors in platypuses, infrared receptors in some snakes, and magnetic-sensitive receptors in birds. The cerebellum likewise varies markedly. In primates the neocerebellar hemispheres are greatly expanded for control of limb movements as well as some aspects of sensory processing. The midbrain roof, or tectum, is also highly variable. Its rostral part, the superior colliculus, is involved in visual localization functions. Of modest size in mammals, it reaches its apogee in birds. The caudal tectum, the inferior colliculus, processes auditory stimuli and is elaborately developed in bats as part of their echolocation sonar system and in birds, such as owls, that hunt in darkness and localize their prey by sound.

Among amniotes, major differences occur in forebrain structure. In mammals, the elaborately layered neocortex (Bock & Cardew, 1999) receives sensory input relayed from dorsal thalamic nuclei, whereas in reptiles and birds, some of the telencephalic cell populations that receive thalamic input are organized as nuclei rather than in layers. Whether these nuclei are equivalent (homologous) to neocortex is an unresolved question (Karten, 1991; Northcutt & Kaas, 1995; Butler & Hodos, 1996; Puelles et al., 2000). All modern mammals are derived from an ancestral stock with somatomotor, auditory, and visual cortical regions occupying similar relative positions on the cerebral hemispheres. Within various orders of mammals, the number of cortical sensory areas has independently increased, and each area has become dedicated to the analysis of specific aspects of the sensory input (Bock & Cardew, 1999). Many primates, for example, have over 20 visual cortical areas that each analyze different aspects and combinations of the visual input. Bats have specialized auditory cortical areas for analyzing the Doppler shift in constant frequency to determine prey velocity and for analyzing frequency modulated sounds with time delay to determine range. Some mammals with prominent whiskers, such as rodents, have specialized, cylindrically shaped regions in the somatosensory cortex called *barrels* that each receive the input from a single whisker.

Neocortex in humans has few truly unique features vis à vis other primate brains. The volume of neocortex relative to the total volume of the brain is only what one would expect for a generalized primate (Passingham, 1979). Language was arguably the most important evolutionary gain for our species (Deacon, 1997), but even here, the parts of the brain used for language comprehension and motor speech have precedent areas in other primates. It is possible that small differences in the volume of cortex in a given region allow for dramatic differences in function. Current research includes new insights gleaned from comparative embryological studies, indicating that small changes in the genome and in the complex developmental program can have profound effects on the phenotype. Some of the most difficult persistent questions concern the complex relationships between cytoarchitecture and function.

BRAIN IMAGING IN AFFECTIVE NEUROSCIENCE

Emotions are action-related feelings of positive or negative valence that are associated with approach or avoidance behaviors and neurophysiological changes. They are learned, innate, or a combination between the two; and they may be transient states such as fear, anger, or happiness; or they may be enduring moods such as depression. Basic knowledge about the neural underpinnings of emotion stems from several decades of animal research utilizing lesion, electrical stimulation, single cell recording, and pharmacological manipulation techniques. During recent years, functional neuroimaging has been applied to study normal and pathological emotions in humans. Together, these streams of research have contributed to the emergence of *affective neuroscience* (Davidson & Sutton, 1995).

Neuroimaging

Brain imaging includes techniques such as electroencephalography (EEG), magnetoencephalography (MEG), positron emission tomography (PET), single photon emission tomography (SPECT), computerized axial tomography (CT), functional magnetic spectroscopy (MRS), and structural (MRI) and functional magnetic resonance imaging (fMRI). Imaging tools may reveal both structure and function and permit measures of electrical, magnetic, metabolic, and neuroreceptor and neurotransmitter characteristics. The first wave of neuroimaging studies concerned basic research on cognitive processes as well as psychopathology, for example, by imaging dopamine receptors in schizophrenic patients or regional cerebral blood flow (rCBF) in individuals with anxiety disorders. A main lesson from the early imaging literature is that the notion of centers, whether cognitive or emotional, is too simplified because even simple tasks may require widespread activation in neural networks.

Affective Style

Imaging studies typically report data that are averaged over groups of individuals. However, individuals vary in quality and intensity of their reactions to similar emotional stimuli. This is often referred to as *affective style* (Davidson & Irwin, 1999), presumably reflecting differences in temperament, personality, and psychopathological vulnerability. Electrocortical studies of affective style have suggested that left frontal brain activity is associated with positive emotions and approach behavior, whereas right frontal activation predicts negative emotions and avoidance. Affective style has also been related to emotionally determined differences in amygdala activation. Activity in the amygdala has been shown to correlate with aversive emotional reactions in general and fear in particular (Davidson & Irwin, 1999).

Emotional Perception and Experience

Emotions may be induced internally though imagination or self-generation, or externally in perceptually driven emotions. Kosslyn and colleagues (1996) reported that the negative emotional content of stimuli increased activity in the occipital cortex both during perception and imagery. Thus, the neural circuits underlying self-generated and perceptually driven emotion may overlap. While self-generated emotions unequivocally involve feelings, perceiving emotion in others may tax cognitive processes rather than generating an emotional experience. Hence, it is important not to equate perception with experience of emotion. Imaging studies of emotional perception have explored the neural networks involved in perceiving facial expressions of primary emotions like fear and disgust presented both consciously and unconsciously, that is, subliminally (Adolphs, 2002). Neuronal activity in the amygdala seems to undergo rapid habituation both in emotional perception and induction studies (for reviews see Whalen, 1998; Davis & Whalen, 2001). It has been argued that the amygdala respond to biologically significant stimuli but predominantly in ambiguous situations (Wahlen, 1998).

Studies of emotional induction have focused mainly on unpleasant emotions, often involving pharmacological probes (e.g., yohimbine, procaine, cholecystokinin tetrapetide [CCK-4] administration) or sensory stimulation using visual (e.g., films or pictures) or auditory (e.g., scripts or tapes) stimuli. Only a small number of studies have extended into other domains such as the olfactory, gustatory, and somatosensory modalities. In an examination of 25 neuroimaging publications on brain and emotion in healthy individuals, Maddock (1999) noted that the inferior frontal

and posterior cingulate cortex, in particular the right retrosplenial cortex, were the regions most frequently activated by emotional conditions.

Emotional Learning and Memory

In classical fear conditioning the emotional impact of a stimulus is altered, that is, it is transformed into a conditioned stimulus capable of eliciting fear reactions after pairings with aversive unconditioned stimuli such as electric shocks. Numerous animal studies support a crucial role for the amygdala in the expression and acquisition of such associative fear memories (Davis & Whalen, 2001). Lesion and neuroimaging studies have indicated that the amygdala is involved in fear conditioning processes in humans as well (Davis & Whalen 2001). The amygdala may also participate in the formation of declarative memory for emotional events (e.g., Cahill et al., 1996). However, the exact role of the amygdala and its subnuclei in the formation and storage of emotional memory is debated and a matter of active research.

Neuropsychiatric Applications

Emotional dysregulation is especially prominent in Anxiety and Mood Disorders. Patients with various Anxiety Disorders have been scanned during symptom provocation to elucidate the pathophysiology of anxiety. Metabolic abnormalities in the orbitofrontal cortex, the cingulate, and the caudate nucleus have been noted in Obsessive-Compulsive Disorder (Rauch & Shin, 1997). For other Anxiety Disorders, findings are mixed although the anterior paralimbic cortex and the amygdala region have been implicated, particularly in Posttraumatic Stress Disorder (Rauch & Shin, 1997), and Social Phobia (Tillfors et al., 2001). The amygdala region may be a common site of action for behavioral and pharmacological treatments of Social Phobia (Furmark et al., 2002).

In major depression, metabolic abnormalities have been reported mainly in the prefrontal, cingulate, amygdala, and thalamic regions. Functional imaging data suggest that depression is associated both with mood-dependent and traitlike neurophysiological abnormalities in brain regions that are at least partly related to anatomical abnormalities revealed by structural imaging techniques (Drevets, 2000).

Studies of pain are also relevant for affective neuroscience because pain regulates mood and motivational behavior. Human pain imaging has shown involvement of the anterior cingulate, anterior insula, and prefrontal and posterior parietal cortices, as well as subcortical regions like the thalamus (Ingvar, 1999). Recent imaging findings suggest that placebo effects mimic brain alterations resulting from opioid analgesia (Petrovic, Kalso, Peterson, & Ingvar, 2002).

Future Directions

While measures of oxygen consumption, glucose metabolism, and regional cerebral blood may reveal the neural correlates of thoughts and feelings, dynamic receptor imaging could enhance our understanding of the associated neurochemistry. By comparing the effect of psychological and pharmacological treatments on receptor or transmitter characteristics, future investigations may reveal whether separate or common neurochemical mechanisms operate. By studying receptor characteristics we could better understand the dynamics of neural transmission during emotional activation and regulation.

BRAIN INJURIES

The brain can suffer injury in diverse ways: metabolic or structural abnormalities that are genetically inherited or perinatally induced; trauma from civilian accidents or military combat; toxicity from drugs, heavy metals, or poisonous gases; malnutrition; infections or diseases; tumors; cerebrovascular accidents (stroke); surgical removal of brain tissue for relief of epilepsy, intractable pain, or serious psychiatric symptomatology; and aging-related disorders (e.g., Alzheimer's disease).

Early perinatal brain lesions tend to be more extensive and diffuse than those incurred later in life. Early lesions often are detected by abnormalities in behavior observed during later development, and the time of onset of the damage can only be approximated in relation to presumed prenatal events. By contrast, lesions incurred beyond infancy often can be linked to a specific event or to an approximate onset in the symptomatology, and premorbid behavior can be compared with postinjury behavior. Some injuries in adulthood can produce clearer abnormalities than others. For example, destruction of an area of the cerebral cortex in the anterior region of the left frontal lobe may cause a noticeable disruption in normal speech, whereas a lesion in the analogous area in the right frontal lobe may produce only subtle changes in emotional functions and personality. Similarly, a lesion in the left frontal lobe near the junction with the parietal lobe can result in loss of language comprehension, but no such problem occurs after an analogous lesion on the right side of the brain.

Brain damage can have divergent effects, depending upon the locus and extent of the damage. For example, clinically it has been noted that lesions in distinctly different areas of the brain will disrupt visual perception at different levels of processing. Damage in the optic nerve, superior colliculi, certain thalamic way stations, and cortex of the occipital lobes will interfere with visual functioning at the level of stimulus input, or processing of stimulus features. Damage in the temporal lobes adjacent to the occipital lobes will disrupt visual perception at a higher level of analysis, such as evaluating the importance or meaningfulness of stimuli, or remembering what the stimuli are. If the damage is on the left side, verbal comprehension of written material (e.g., reading) is impaired. Finally, damage in the frontal lobes may interfere with the expression of responses to stimuli. Not surprisingly, left frontal damage can interfere with language expression (e.g., speaking or writing words).

Because brain damage does not always result in immediately apparent symptoms, localization of the site and extent of damage may be difficult. For example, while an analysis of a specific sensory function, such as the integrity of the visual fields, can reveal basic sensory defects, more subtle cognitive and intellectual defects may require careful scrutiny. Functions involved in attention, motivation, emotion, and language often must be measured through the skillful administration and interpretation of tests specifically designed to show the impairments. Descriptions of many of these tests can be found in books by Lezak (1995), Mesulam (2000), and Spreen and Strauss (1998), as well as in a chapter by Oscar-Berman and Bardenhagen (1998).

Accidental head trauma, generally called *traumatic brain injury* or *TBI,* is a common yet severely disabling disorder. Because of the shape of the skull and the way the brain rests inside this bony case, violent blows to the head often seriously impact the prefrontal cortex and its connections with other brain regions. Severe frontal dysfunction leads to relaxed inhibitory control over appetitive or sexual drives and thus to inappropriate social behaviors that can prevent the TBI patient from returning to full functional independence.

Neurologists rely on a variety of imaging and recording techniques for visualizing brain abnormalities in their patients. The techniques are used to measure parameters such as cerebral blood-flow patterns and obstructions, ventricular size, regional glucose utilization, the presence of abnormal tissue masses, and seizure activity. Such techniques include angiography, X-ray computerized tomography (CT scans), structural and functional magnetic resonance imaging (MRI and fMRI scans), positron emission tomography (PET scans), single photon emission computed tomography (SPECT scans), electroencephalography (EEG), evoked potentials (EP), and magnetoencephalography (MEG). Each technique provides the neurologist and neuroscientist with a particular type of information about the structure or function of the brain. The various techniques also are used to monitor changes in the brain with the progression of a disease, or during recovery from an illness.

Some techniques use X rays to reveal images of abnormal blood flow through cerebral arteries (carotid angiography) or lesions produced by stroke or brain tumors (CT scans). MRI scans provide images of the brain without X rays, and because of the nature of the magnetic signals that produce MRI images, the scans can easily visualize small tumors, multiple sclerosis plaques, and infarctions. Another group of imaging techniques such as PET, SPECT, and fMRI provide images of regional cerebral blood flow, blood volume, or glucose metabolism, all of which are closely coupled and correlated with neuronal activity and are thus indirect measures of brain functioning. Normal

electrical changes in the brain, as well as abnormal electrical activity such as in epilepsy, can be measured with another set of techniques, which include EEG, EP, and MEG. These procedures generally entail the attachment of electrodes to the scalp at standard locations in order to pick up electrical signals reflecting brain functioning. The signals are amplified and interpreted for the presence of abnormalities. For a comparison of various neuroimaging techniques, see a recent paper by Dale and Halgren (2001).

BRAIN SPECIALIZATION

Specialization and Integration

The brain adheres to two fundamental principles of organization, *functional integration* and *functional specialization.* The integration among specialized cortical areas depends upon cortico–(sub)cortical connections and the neuronal interactions they mediate. The characterization of functional specialization is important in many areas of neuroscience and provides an infrastructure within which normal brain function can be understood (e.g., cognitive neuroscience) and how things might go wrong (e.g., neuropsychology and clinical neuroscience). The distinction between specialization and integration relates to the distinction between localizationism and (dis)connectionism that dominated thinking about brain function in the nineteenth century. Since the early anatomic theories of Gall, the identification of a particular brain region with a specific function has become a central theme in neuroscience. However, functional localization per se was not easy to demonstrate: for example, a meeting entitled "Localization of Function in the Cortex Cerebri" in 1881 addressed the difficulties of attributing function to a cortical area, given the dependence of cerebral activity on underlying connections (Phillips, Zeki, & Barlow, 1984). Goltz (1881), although accepting the results of electrical stimulation in dog and monkey cortex, considered the excitation method inconclusive in that the movements elicited might have originated in related pathways or current could have spread to distant areas. In short, the excitation method could not be used to infer functional localization because localizationism discounted interactions among areas. It was concluded that lesion studies should supplement excitation experiments. Ironically, it was observations on patients with brain lesions (Absher & Benson, 1993) some years later that led to the concept of disconnection syndromes and the refutation of localizationism as a sufficient account of cortical organization.

Functional localization implies that a function is localized in an area, whereas specialization suggests that a cortical area is specialized for some aspects of cognitive, perceptual, or sensorimotor processing. The cortical infrastructure supporting a single function may involve many specialized areas whose union is mediated by functional integration. In this view functional specialization is only meaningful in the context of functional integration and vice versa.

The Nature of Functional Specialization

The functional role played by any component (e.g., cortical area, subarea, or neuronal population) of the brain is defined by its connections. Certain patterns of cortical projections are so common that they could amount to rules of connectivity. "These rules revolve around one, apparently, overriding strategy that the cerebral cortex uses—that of functional specialization" (Zeki, 1990). Functional specialization demands that cells with common functional properties be grouped together. This architectural constraint necessitates both convergence and divergence of cortical connections. Extrinsic connections between cortical regions are not continuous but occur in patches or clusters. This patchiness has a clear relationship to functional specialization. For example, a visual area at the back of the brain (V2) has a distinctive cytochrome oxidase staining pattern, consisting of thick stripes, thin stripes, and interstripes. When recordings are made in V2, directionally selective (but not wavelength- or color-selective) neurons are found exclusively in the thick stripes. Retrograde (i.e., backwards) labeling of cells in a functionally homogeneous area that is specialized for visual motion (V5) is limited to these thick stripes. Evidence of this nature supports the notion that patchy connectivity is the anatomical substrate of functional specialization. If neurons in a given area share a common responsiveness (by virtue of their connections) to some sensorimotor or cognitive attribute, then this functional specialization is also an anatomical one.

The search for specialized cortical areas still rests upon the axis established in the nineteenth century, namely the lesion-deficit model and brain excitation methods. Current

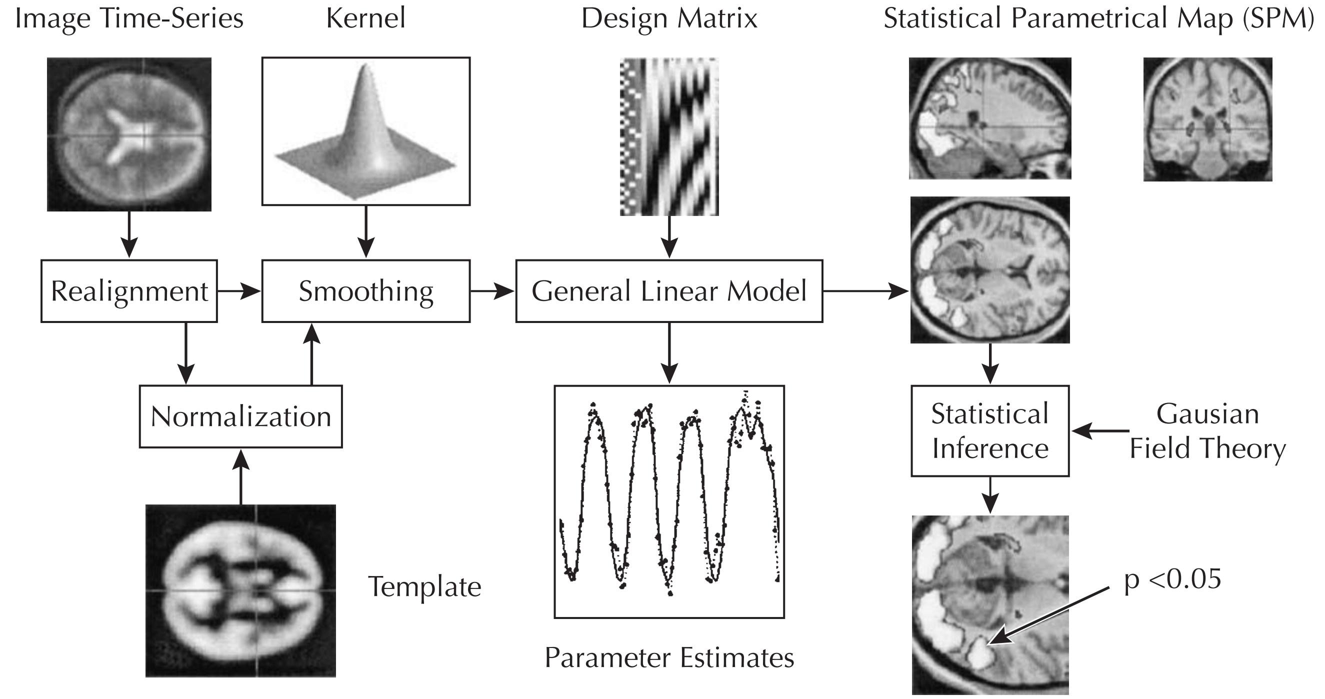

Figure 1. Mapping specialization in the brain.
The transformations that constitute an analysis of functional images create a statistical parametric map (SPM). SPMs can be thought of as X rays of the significance of an effect (e.g., activation in a specialized area revealed by subtracting scans obtained in one condition from those obtained in another). After realignment the images are subject to nonlinear warping to match a template that conforms to some standard anatomical space. After smoothing, the general linear model is employed to perform the appropriate statistical test at every voxel (i.e., volume element). The test statistics that ensue (usually *t*- or *F* statistics) constitute the SPM. SPMs are used to make inferences about brain responses that are then characterized using the fitted responses or parameter estimates. Adjustments to *p*-values, for the enormous number of tests implicit in an SPM, are usually made using distributional approximations from the theory of Gaussian fields.

approaches rely on (1) the functional deficits following circumscribed brain injury (neuropsychology), and (2) functional neuroimaging. Although important, the inferences about neuronal architectures, based solely on the lesion-deficit model, are fundamentally limited. The integration of neuropsychology, psychophysics, and neuroimaging has revolutionized our view of the brain, literally and conceptually. Challenging subjects with the appropriate sensorimotor attribute or cognitive process leads to activity changes in, and only in, the relevant specialized areas. This is the model upon which functional imaging is based.

Specialization and Functional Imaging

The tenet of functional neuroimaging is that the difference between two tasks can be formulated as a separable cognitive or sensorimotor component and that the regionally specific differences in brain activity identify the corresponding specialized area. The first applications addressed the functional anatomy of word processing (Peterson, Fox, Posner, Mintun, & Raichle, 1989) and functional specialization in extrastriate cortex (Lueck et al., 1989). The latter studies involved presenting visual stimuli with and without some sensory attribute (e.g., color, motion, etc.). The areas highlighted, by comparing the ensuing scans, were identified with homologous areas in monkeys that showed selective electrophysiological responses to equivalent stimuli. Most studies of functional specialization employ statistical parametric mapping (Friston, 1997) to provide what can be thought of as X rays of significant brain responses (see Figure 1). These statistical parametric maps (SPMs) are constructed using a series of brain scans acquired from subjects under experimentally induced changes in brain state, designed to isolate the function of interest. The cortical area in the lower right of Figure 1 is visual area V5 and shows significant motion-sensitive responses elicited by alternate presentations of stationary and moving dots.

BRAIN STEM

The brain stem, which consists of the midbrain, pons, and medulla oblongata, connects the cerebrum above to the spinal cord below. It is a highly organized structure that, in addition to conveying ascending and descending tracts, contains the nuclei of the cranial nerves III to XII and is responsible for a number of complex functions, including control of respiratory and cardiovascular activity and regulation of the level of consciousness.

The *midbrain* is the shortest segment of the brain stem. It consists of a ventral and a dorsal portion separated by the ventricular space. The dorsal or posterior portion is called the *tectum* and consists of four rounded swellings, the paired superior and inferior colliculi. The ventral or anterior portion is called the *tegmentum* and contains the reticular formation, the nuclei of cranial nerves III and IV, and ascending and descending pathways.

The *pons* is readily identified from the midbrain and from the medulla oblongata (whose description follows) as a large bulge on the ventral surface of the brain stem lying on the dorsum sellae of the sphenoid bone. The dorsal or posterior surface of the pons is taken up superiorly by the superior cerebellar peduncles, while inferiorly it forms the upper part of the floor of the fourth ventricle. The pons contains ascending and descending tracts and connections with the cerebellum, as well as the nuclei of cranial nerves V to VIII.

The *medulla oblongata* extends from the lower limit of the pons to a level just above the first pair of cervical nerves, where it is continuous with the spinal cord. It is somewhat pyriform in shape, larger superiorly than inferiorly. The dorsal surface of the medulla oblongata forms the lower part of the floor of the fourth ventricle in the cephalad half. The ventral surface is made up of the pyramids containing the corticospinal tracts. The medulla oblongata contains the nuclei of cranial nerves IX through XII, which exit along its lateral aspects. The caudal half of the medulla oblongata represents a transition to the spinal cord, with cross-sectional organization and a central canal similar to the cord.

Given the complexity of the structure of the brain stem and the proximity of the motor and sensory tracts and cranial nerve nuclei, it is not surprising that disturbances in brain-stem function can be seen with very small lesions. Until the advent of computerized tomography (CT) in the late 1970s, the brain stem could be imaged only by indirect means. Even CT is not ideal, primarily because of distortions of the image caused by the surrounding bone. Magnetic resonance imaging (MRI) is now the imaging modality of choice for patients in whom a lesion in the brain stem is suspected.

Lesions that may affect the brain stem include vascular malformations such as angiomas, which may be a cause of spontaneous hemorrhage; infectious diseases such as tuberculosis, although this is rare in developed countries; demyelinating diseases such as multiple sclerosis; and tumors.

Classically occurring in children at a median age of between 5 and 10 years, brain-stem tumors account for as many as 15% of all brain tumors in this age group. Evidence suggests that the incidence of brain-stem tumors has been increasing, although this is probably due in large part to better detection using MRI of lesions that in the past may have gone undiagnosed.

There are several types of brain-stem tumors, each characterized by a distinct clinical presentation and MRI appearance. These include focal tumors, most often seen in the midbrain; dorsal exophytic tumors that grow from the dorsal aspect of the medulla into the fourth ventricle; and cervicomedullary tumors that originate in the upper cervical cord or medulla and grow posteriorly to project into the fourth ventricle. These types account for approximately 20% of all brain-stem tumors. Some, notably focal tumors arising in the tectum, may do well without any therapeutic intervention. Others may do well after surgery alone or, if this is not possible, after treatment with radiotherapy. In contrast, approximately 80% of all brain-stem tumors are of the so-called “diffuse intrinsic kind.” These are high-grade astrocytomas that grow very rapidly and cause multiple neurological deficits. Surgery is not indicated, and these patients are treated with radiotherapy alone. In spite of a satisfactory early response to treatment, outcome is very poor. The median time to progression after treatment with radiotherapy is only of the order of 6 months, and the median survival time is less than 1 year. Less than 10% of patients will be alive 2 years or more after treatment. Several groups are actively undertaking research studies using various types and combinations of chemotherapy and biological agents given along with radiotherapy in the hope

of achieving an improved outcome for children with these tumors, as yet without success.

BUFFERING HYPOTHESIS

The buffering hypothesis asserts that social support provides protection against the stress that produces psychological or physiological disorder or disease or reduces job performance. The stress-buffering function of social support has been of considerable interest to behavioral and medical scientists, especially since a 1979 Alameda County study showed that social conditions, such as marriage and group membership, were related to mortality.

Several issues emerge in research on the buffering hypotheses. Of particular importance is the definition and measurement of three variables: stress, social support, and outcome. Psychological *stress* is often measured on a checklist or inventory by self-report of major life events of the last few months, such as death in the family, divorce, and changes in work. Using weights from experts' ratings of stress, the experimenter obtains a total score. A less used kind of measure is called *daily hassles,* such as burdensome household chores and waiting in traffic. *Social support* is measured in three ways: (1) social network membership (sometimes called social integration), such as living with a family, belonging to a club, or attending a church; (2) perceived social support, such as self-report of availability of people to discuss problems or provide material aid; and (3) support behaviors, such as reported or observed actions of helping the specified person. The first two methods have received the most research attention. The *outcome* or dependent variables are usually physical or psychological disorders (or health), such as depression, recovery from surgery, smoking cessation, and development of cancer or AIDS symptoms in infected people. Productivity may be used as an outcome in industrial settings.

In general the findings across many studies with the first two social support measures have been positive. In a 1991 review, Sheldon Cohen (pp. 1–2) concluded, "The epidemiological data on the role of social integration in morbidity and mortality have clearly established that the social environment plays an important role in health and well being . . . [and] when a perceived availability of a social support measure is used, these effects reliably occur in the prediction of psychological and physical symptoms." It appears that the body's immune system is affected by social support, and people who get colds readily are likely to have poor social supports. An overview of abstracts of articles since Cohen's conclusions show a majority of studies with positive results, but not all. A few studies of animals also support the buffering hypothesis.

Beyond these generally positive findings, many theoretical and research questions remain. One is the issue of whether the results are due to main effects or buffering effects. Is social support a true buffering effect having no influence of its own but being entirely conditional upon the presence of stress? Another related issue is the place of social support in the chain of multiple cause and effect as represented in the diathesis-stress theories of psychopathology. *Diathesis* refers to predispositions to disorder from biological or early experiential causes. Throughout the life cycle, social support and nonsupport interact with other variables to protect or not protect against stress.

An important theoretical task in clarifying the buffering hypothesis is the integration of the many possible variables into a model explaining why social support works. Cohen has presented a transactional model that includes core concepts about social networks, stressful events, and personality factors, including perceived social support, stress appraisal, and support behaviors ultimately affecting the development of a disorder. Basing his conclusion on several studies, Cohen indicates that one personality feature that seems particularly important to include in addition to social support is the sense of internalized control or self-efficacy (a person's sense of capability and effectiveness). Coping styles and genetic predispositions are other psychological variables that need to be included in an integrated theory of the relation between stress and disorder surrounding the buffering hypothesis.

On a larger than individual scale, community settings and institutions, such as churches, schools, and senior centers, can provide buffers for stress. Group interventions, such as workshops on stress inoculation for people in dangerous occupations or students facing examinations, may provide social support as well as increasing self-efficacy.

BULIMIA

Bulimia, more accurately known as Bulimia Nervosa, is an eating disorder characterized by three primary symptoms: recurrent episodes of binge eating, inappropriate compensatory behaviors, and extreme concern about body weight

and shape. Binge eating involves the consumption of a large amount of food in a relatively short period of time along with a perception of loss of control over eating. Binge eating may be triggered by a number of factors, including hunger, negative mood, interpersonal stressors, and thoughts about weight and shape. Inappropriate compensatory behaviors are strategies aimed at controlling body weight and shape, including self-induced vomiting, misuse of laxatives and/or diuretics, excessive exercising, and fasting. The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV;* American Psychiatric Association, 1994) divides Bulimia Nervosa into two subtypes. The *purging* subtype is distinguished by the presence of purging compensatory behaviors such as self-induced vomiting or laxative misuse. The *nonpurging* subtype is diagnosed in the presence of only nonpurging compensatory behaviors (e.g., excessive exercise). Individuals with Bulimia Nervosa also exhibit overconcern about their body weight and shape and usually engage in extreme dietary restriction outside of binge-eating episodes in order to control weight and shape. The dysfunctional concerns about weight and shape are typically conceptualized as the central feature or core psychopathology of Bulimia Nervosa.

Bulimia Nervosa typically begins with rigid and unhealthy dieting that is motivated by the desire to be thin and lose weight. Individuals with Bulimia Nervosa attempt to limit the amount and type of food that they consume, particularly during the early stages of the disorder. Over time, they become increasingly preoccupied with thoughts of food, and episodes of binge eating alternate with periods of restriction. Vomiting, laxative misuse, and other inappropriate compensatory behaviors usually follow the onset of binge eating.

Bulimia Nervosa most commonly occurs in women and usually begins in adolescence or early adulthood. Approximately 1–2% of young women meet criteria for the disorder. In contrast to Anorexia Nervosa, individuals with Bulimia Nervosa maintain normal weight. As a result, Bulimia Nervosa is more difficult to detect than Anorexia Nervosa as physical signs are not readily apparent to the casual observer. Bulimia is often a secretive disorder, and individuals with Bulimia Nervosa typically experience guilt and shame about their behavior. Individuals with Bulimia Nervosa display rigid patterns of thinking and tend to view the world and their experiences from an "all or nothing" perspective. For example, bulimics often describe eating as being either "in control" or "out of control" and weight or appearance as either "thin" or "fat."

The medical complications associated with Bulimia Nervosa are generally regarded as less severe than those associated with the low body weight of Anorexia Nervosa. Electrolyte disturbances represent the most serious medical complication and may lead to cardiac irregularities and, in some cases, heart failure. Inflammation and rupture of the esophagus is another serious potential complication resulting from repeated vomiting. Additional medical complications include laxative dependence, fatigue, enlargement of salivary glands leading to puffy cheeks, headaches, dry skin, abrasions to fingers from inducing vomiting, and dental erosion.

Numerous causal factors have been proposed as being related to the development of Bulimia Nervosa. Disturbances in such neurotransmitter systems as those of serotonin and norepinephrine have been observed, but it remains unclear whether these biological irregularities cause Bulimia Nervosa or result from the disturbed eating behaviors that characterize the disorder. Findings from several studies suggest that Bulimia Nervosa may result, in part, from dieting-based changes in serotonin functioning in vulnerable individuals. Neurochemical abnormalities appear to persist after recovery. A genetic basis for bulimia is supported by family studies, which examine the clustering of disorders within families. Family studies find increased rates of eating disorders in the families of individuals with Bulimia Nervosa as compared to the families of individuals without Bulimia Nervosa. The exact role genetic factors play in the development of Bulimia Nervosa, however, remains unclear, and environmental factors clearly influence the development of the disorder.

Although it is widely believed that childhood sexual abuse causes Bulimia Nervosa, there is little evidence for a specific relationship between a history of sexual abuse and the development of the disorder. Childhood sexual abuse appears to increase one's risk for psychological disorders in general, not Bulimia Nervosa specifically. Cultural factors do appear to play a role in the development of Bulimia Nervosa. The ideal female weight in Western society, often referred to as the *thin ideal,* has continued to decrease even as the average female weight increases. As a result, more and more women experience normative body dissatisfaction secondary to a discrepancy between their ideal and actual weight. Body dissatisfaction is widespread among adolescent girls, and research links body dissatisfaction, along with acceptance of the thin ideal, to the development of Bulimia Nervosa. Prospective research has also found a strong relationship between dieting and the later development of an eating disorder. Other potential risk factors include early onset of menstruation, a personal or parental history of obesity, parental dieting, and personality traits such as perfectionism. Bulimia Nervosa often co-occurs with other psychological disorders including depression, Anxiety Disorders, substance abuse disorders, or some Personality Disorders such as Borderline Personality Disorder.

According to the *DSM-IV,* Bulimia Nervosa is typically either intermittent, with binge eating and/or purging alternating with periods of remission, or chronic. Treatment, however, can significantly affect outcome. Cognitive-behavioral therapy (CBT), a psychological treatment, is widely viewed as the treatment of choice for Bulimia Nervosa. CBT for Bulimia Nervosa includes education about Bulimia Nervosa, self-monitoring of eating behaviors, establishing a regular pattern of eating, strategies to reduce binge eating and compensatory behaviors (e.g., vomiting),

problem solving, and cognitive restructuring. Cognitive restructuring is a strategy designed to help patients identify and challenge their patterns of thinking. Numerous studies have demonstrated that the majority of patients treated with CBT benefit from treatment and that improvement is maintained over time. Interpersonal psychotherapy is another psychological treatment that is supported by research, although fewer studies have examined this form of psychotherapy. Antidepressant medications also appear to reduce bulimic symptoms.

BUROS MENTAL MEASUREMENTS YEARBOOK

As a young professor at Rutgers University in the mid-1930s, Oscar Krisen Buros developed the idea for a book series that would insure test users an indispensable reference for in-depth descriptions and critiques of all commercially produced tests developed in the English language. Soon to become *The Mental Measurements Yearbook* (*MMY*) series, his publication of "candidly critical" reviews of tests, Buros believed, would serve a variety of public interests. For test users, the series would afford valuable access to the expertise of scholars and professionals. Buros also held that test users would gradually become informed consumers of testing products and would increasingly select tests that met or exceeded minimal standards of psychometric adequacy. For test designers and publishers, Buros maintained that the publication of critical reviews would "cause authors and publishers to publish fewer but better tests" (Buros, 1938, p. xiii).

Buros was undaunted by substantial pressures to curtail publication of the *MMY* series. The logistics of recruiting qualified professionals and securing their reviews for large numbers of testing instruments promised to be (and has remained) an enormous undertaking. In addition, test authors and publishers sometimes provided limited cooperation for securing information about tests and related testing materials. Occasionally, Buros was threatened with lawsuits over critical reviews. To sustain him in this endeavor, Buros enlisted the considerable talents of his wife, Luella, and small group of devoted staff. Funding to create a consumer's research bureau whereby specially trained teams of psychometricians would independently evaluate tests did not materialize. Instead, Buros continued to rely upon large numbers of academics and specialized professionals to serve in the role of test reviewers.

Despite the name *The Mental Measurements Yearbook* and the desire of its editor to publish new volumes annually, the exacting standards of Buros and the size of the undertaking mandated a production schedule for the *MMY* averaging once every 5 years. Besides the publication of the *MMY,* Buros also edited special monographs on testing in distinct subject areas (e.g., vocations, personality) and initiated production of the *Tests in Print (TIP)* series. *TIP* was designed to serve the testing community as a compendium of all currently available tests and to provide a quick reference to test reviews published in the *MMY* series. Whereas new editions of the *MMY* both describe and review new tests, each edition of the *TIP* series contains descriptive entries of all known tests currently available in the English language.

The publication process for the books edited by Buros began with *Educational, Psychological, and Personality Tests of 1936* and *The 1938 Mental Measurements Yearbook* and had continued through *The Eighth Mental Measurements Yearbook* (1978) when Buros passed away. After a nationwide search to determine a successor location, Luella Buros selected the University of Nebraska-Lincoln to continue the work begun by her late husband over 40 years earlier. The world's largest collection of tests and testing material was subsequently crated and shipped to a new location halfway across the United States. Publication commenced in 1983 with *Tests in Print III,* followed soon afterward by *The Ninth Mental Measurements Yearbook.*

The dream of Oscar Buros for fewer, better quality tests has been partially realized in several ways. A current count of in-print tests has suggested a small reduction in the number of commercially available instruments being offered for sale since 1983. In addition, many of the sophisticated methodological strategies designed to insure test reliability, validity, and appropriate standardization had not been developed in the days when Buros made his initial proclamation on tests. With the advent of testing standards first articulated in 1954 (and most recently in 1999) by the American Educational Research Association, the American Psychological Association, and the National Council on Measurement in Education, test authors and publishers alike have greater guidance by which to judge the adequacy of their products.

Shortly before her death in 1995, Luella Buros funded the Buros Center for Testing. Mrs. Buros believed that, in order to speed advances in the field of testing and measurement, it was essential to create a consultation service that would share test development expertise with both the public and private sectors. Working as the umbrella organization, the center has acted to combine the historic objectives of the Buros Institute of Mental Measurements for improved testing with consultation services from the newly created Buros Institute for Assessment Consultation and Outreach.

In response to continual requests to make test reviews more accessible to the public, *Test Reviews Online* was launched in September, 2001. This Internet service (available at *www.unl.edu/buros*) was designed to provide, for a modest fee, immediate access to over 2,000 testing instruments in a wide variety of subject areas. Additional test reviews are being added each month. The Buros Center for Testing continues the work of improving tests and assessments that was first articulated by Oscar Buros over 65 years ago.

Brief History of the Buros Institute of Mental Measurements

1938—*The 1938 Mental Measurements Yearbook;* Oscar K. Buros (Editor)

1940—*The 1940 Mental Measurements Yearbook;* Oscar K. Buros (Editor)

1949 to 1978—The third through eighth *Mental Measurements Yearbooks,* and *Tests in Print* and *Tests in Print II;* Oscar K. Buros (Editor)

1978—Oscar K. Buros passes away. Luella Gubrud Buros relocates the Buros Institute of Mental Measurements to the University of Nebraska-Lincoln.

1983 to 1985—*Tests in Print III* and *The Ninth Mental Measurements Yearbook;* James V. Mitchell, Jr. (Editor)

1989—*The Tenth Mental Measurements Yearbook;* Jane Close Conoley & Jack J. Kramer (Editors)

1992—*The Eleventh Mental Measurements Yearbook;* Jack J. Kramer & Jane Close Conoley (Editors)

1994—The Oscar and Luella Buros Center for Testing is created as a parent organization, adding the Buros Institute for Assessment Consultation and Outreach to the Buros Institute of Mental Measurements. *Tests in Print IV;* Linda L. Murphy, Jane Close Conoley, & James C. Impara (Editors)

1995—*The Twelfth Mental Measurements Yearbook;* Jane Close Conoley & James C. Impara (Editors)

1998—*The Thirteenth Mental Measurements Yearbook;* James C. Impara & Barbara S. Plake (Editors)

1999—*Tests in Print V;* Linda L. Murphy, James C. Impara, & Barbara S. Plake (Editors)

2001—*The Fourteenth Mental Measurements Yearbook;* Barbara S. Plake & James C. Impara (Editors). *Test Reviews Online* (a collection of over 2,000 recent test descriptions and reviews from *The Mental Measurements Yearbook* and *Tests in Print* series) becomes available via the Internet.

2002—*Tests in Print VI;* Linda L. Murphy, Barbara S. Plake, James C. Impara, & Robert A. Spies (Editors)

2003—*The Fifteenth Mental Measurements Yearbook;* Barbara S. Plake, James C. Impara, & Robert A. Spies (Editors) with subsequent editions to be completed at 18-month intervals

BYSTANDER INVOLVEMENT

In March 1964 Kitty Genovese was brutally murdered in New York while 38 of her neighbors watched from their apartment windows. Even though the attack lasted over 30 minutes, no one called the police until it was over. As a direct result of this incident, a great deal of empirical and theoretical knowledge has been generated on the topic of bystander involvement.

According to a model developed by Latane and Darley (1970), the decision to intervene consists of a series of decisions. First, the bystander must notice that something is happening. Second, the bystander must interpret or label what has been noticed as an emergency. Third, the bystander must decide that he or she has a responsibility to become involved. Fourth, the bystander must decide what form of assistance to render. And fifth, the bystander must decide how to implement the previous decision. Research findings supporting the model attest to the important role played by social influence factors at two stages of the model—labeling the event as an emergency and feeling responsible for becoming involved. Bystanders may use the actions of others in the situation to help them interpret the event. If the others are unsure themselves about what is happening and hesitate to take action, each may use this seeming passivity of others to label the event as a nonemergency. Even when a bystander is certain that the event is an emergency, the presence of others may diffuse responsibility for taking action. As a result, bystanders are less likely to aid the victim. This diffusion of responsibility explanation of bystander involvement is supported by a wide range of empirical findings showing that the greater the number of bystanders present, the less likely a victim is to receive aid (Latane & Nida, 1981).

Another model of bystander involvement for which there

is considerable empirical support is the Arousal: Cost-Reward Model first proposed by I. M. Piliavin, Rodin, and J. A. Piliavin (1969), and more recently expanded to cover nonemergency helping (J. A. Piliavin, Dovidio, Gaertner, & Clark, 1981). The model consists of two components—an arousal component and a cost-reward component. The components are conceptually distinct but functionally related. The model proposes that bystanders are aversively aroused by the victim's distress, that they are motivated to reduce their arousal, and that helping the victim is one way to accomplish this. According to the model, "arousal is a function of the clarity and severity of the crisis and of the psychological and physical closeness of the bystander to the victim" (Dovidio, J. A. Piliavin, Gaertner, Schroeder, & Clark, 1991, p. 89). In their search for ways to reduce their arousal, bystanders are guided by their assessment of the rewards and costs of each option. The model proposes that they will prefer responses that most rapidly and completely reduce arousal and that yield the most favorable costs-rewards ratio. For example, the costs of intervening could include effort and physical harm, whereas rewards could include feelings of efficacy and expressions of gratitude from the victim.

The model is sufficiently broad to account for the influence of a wide array of personality and situational variables. A recent review of relevant research indicates strong empirical support for many aspects of the model (Dovidio et al., 1991). While successive versions of the model have added to its breadth, the model has become increasingly complex (the current version has eight boxes and 17 arrows), making causal analysis more difficult.

Batson and his colleagues have challenged the Arousal: Cost-Reward Model, claiming that it assumes bystanders are egoistically motivated (Batson, 1987). That is, it assumes that bystanders' primary concern is to reduce their own distress and helping the victim is a means for achieving this goal. In contrast, Batson proposes a model of helping based on empathic concern. According to his Empathy-Altruism Hypothesis, witnessing another individual in distress can lead to empathic concern, involving feelings of sympathy, compassion, and tenderness. Such emotions can "evoke motivation with an ultimate goal of benefitting the person for whom the empathy is felt—that is, altruistic motivation" (Batson, 1998, p. 300). In a series of experiments that controlled for alternative egoistic motivation, Batson (1987) demonstrated strong support for altruistically motivated helping. The research thus suggests that there can be multiple motives for bystanders' reactions and that their helping behavior can best be viewed as a weighted function of egoistic and altruistic motives.

Two important moderators of bystander reactions are attributions and type of relationship. The types of attributions bystanders make about the victim and about themselves (e.g., their arousal) can influence their helping behavior. For example, bystanders have been found to be less likely to aid a victim if they view the victim as being responsible for his or her fate (Lerner, 1980). The type of relationship that the bystander has with the victim can also moderate helping. Bystanders who feel a sense of "we-ness" with the victim, or who are in a communal relationship with the victim (Clark & Mills, 1979), may feel more empathy for the victim and thus experience greater arousal and distress than bystanders who perceive the victim as being different or as being a member of an out-group.

Personality factors have been found to provide a poorer accounting of bystander involvement than have features of the situation. Although there has been some recent success in identifying dispositional predictors of helping, correlations rarely exceed 0.30–0.40, leaving about 85–90% of the variance unaccounted for (Batson, 1998).

C

CANADIAN PSYCHOLOGICAL ASSOCIATION

A motion creating the Canadian Psychological Association (CPA) was moved and passed at a dinner meeting in Ottawa in June 1938, which was held in conjunction with a meeting of the American Association for the Advancement of Science. Subsequently, a constitution was adopted in December 1940; however, the usual date reported for the inception of the organization is 1939. There were 38 founding members. Although there is some debate about the impetus for the establishment of the CPA, one school of thought holds that the organization was created so that psychologists might contribute more effectively to the war effort.

In general the CPA's mandate is to represent the interests of and provide leadership in all aspects of psychology in Canada. More particularly, CPA aims to promote the unity, coherence, and sense of identity among the diverse scientific and professional interests and geographical disparities of all psychologists in the country. Current members number over 5,100. Full members must possess a master's degree in psychology, while student members may be graduate or undergraduate students studying psychology on a full- or part-time basis. Affiliates are those who have shown an active interest in psychology and have all the perks of membership but may not hold office.

The governance of the CPA consists of an appointed honorary president plus an 11-person board of directors (including the president, president elect, and past president) assisted by an executive director and head office staff. (Administrative offices are located in Ottawa.) Two directors, one representing the Canadian Society for Brain, Behaviour, and Cognitive Science and the other the Council of Canadian Departments of Psychology, have designated seats, while other directors and the president are elected. The Council of Provincial Associations of Psychologists (CPAP), the Canadian Council of Professional Psychology Programs, and the Association of State and Provincial Psychology Boards enjoy observer status at board meetings. Various functions are assigned to committees of the board, with a director serving as chair. Included among the 15 extant committees are By-Laws, Rules and Procedures; Convention; Education and Training; Ethics; Fellows and Awards; International Relations; Membership; Professional Affairs; Publications; Scientific Affairs; and Sections. There are 24 sections affiliated with the CPA that span the myriad subspecialties in the discipline, from Adult Development and Aging to Women and Psychology. These sections have official status under the bylaws and are the primary agents through which the particular and special needs of members are met and interests served. The CPA also maintains close ties with provincial associations of psychologists and regulatory bodies through membership on CPAP.

The CPA publishes three scholarly journals (*Canadian Psychology, Canadian Journal of Behavioural Science,* and *Canadian Journal of Experimental Psychology*), each of which produces four issues annually. A newsletter, *Psynopsis,* sent to all members, also appears four times a year. Access to these publications is available online for members. More episodic publications include the Strengthening Psychology series. This series consists of relatively brief articles, commissioned by CPA, that address specific issues in the health care field (e.g., home and community care, medicare, pharmacare, and primary care). The organization has also been active in the development of national standards and ethical principles, and a number of documents pertain to these efforts (e.g., *A Canadian Code of Ethics for Psychologists,* 1991; *A Companion Manual of the Canadian Code of Ethics for Psychologists,* 1992; *Guidelines for Non-Discriminatory Practice,* 1996; *Guidelines for Therapy and Counselling with Women,* 1980; *Guidelines for Professional Practice for School Psychologists,* 2002). A number of position statements have also been approved by CPA members over the years recognizing the legitimacy of psychology of women courses and research, the need for more affordable quality child care, opposition to the reintroduction of the death penalty, and various other matters. The Association also maintains a web site at http://cpa.ca.

The CPA annually hosts a 3-day convention with a varied program of invited speakers, symposia, and paper and poster sessions. A number of continuing education workshops typically precede the convention proper. Sections and committees hold their annual business meetings at the convention, and sections have significant responsibilities for convention content. Another publication of the CPA is the annual convention issue of *Canadian Psychology,* which contains abstracts of convention submissions.

In addition to recognizing the contributions of members through election to fellowship, the CPA offers a number of other awards for distinguished contributions to the application of psychology; to public or community service; to psychology as a profession; to psychology as a science; and to

education and training in psychology. There are also a number of New Researcher awards and a Gold Medal award for lifetime contributions to Canadian psychology. Students producing outstanding honors, master's, and doctoral theses at each university across the country are recognized with a Certificate of Excellence award. Many sections also provide awards; several of these are designed to applaud the best student presentation at the convention.

One of the many important functions performed by the CPA is the accreditation of university-based professional doctoral programs in clinical, clinical neuropsychology and counselling (22 accredited), and predoctoral internship programs (26 accredited). A recent initiative of the CPA is the inauguration of the CPA Foundation. Donations to the Foundation are intended to provide support for students in psychology, for psychological research, and for public policy development. A mentoring program for junior faculty is another member service offered by the CPA. The purpose of this initiative is to offer new academic faculty an opportunity to contact and communicate with more experienced, tenured colleagues (from another university) who are willing to provide advice and direction relevant to the role of a university professor.

Representing psychology to the government is a priority of the CPA. The CPA has maintained a high profile in both consulting and lobbying with the Canadian federal government on issues affecting the ability of psychology to contribute to the welfare of Canadian society (for example, in the areas of health, the criminal justice system, research funding, and education). This work frequently represents collaborative efforts with other groups such as the Canadian Consortium for Research and the Health Action Lobby. *Psychology and Public Policy: An Advocacy Guide for Psychologists* (1999) and *Working With the Media: A Guide for Psychologists* (2000) are excellent how-to documents designed to encourage greater political participation on the part of Canadian psychologists.

In the interests of fulfilling its mandate of fostering cohesion among the disparate national and provincial organizations of psychology, the CPA has been an active participant, along with 17 other organizations, in seeking to integrate these diverse groups so that Canadian psychology might speak with one voice.

CAREER COUNSELING

Career counseling is one of several interventions used to assist clients with career issues and problems. Other interventions include career appraisal and testing and the use of computer-assisted career guidance systems, the Internet, job simulations, gaming, and a variety of self-directed initiatives designed to help clients clarify their personal strengths and weaknesses, as well as their aptitudes, interests, values, personality types, and aspirations. Both self-directed and counselor-directed processes focus on helping the client explore available jobs, occupations, and other career options, evaluate them, and examine their congruence with client preferences and abilities.

Historically, career counseling was treated as separate from psychotherapy or personal counseling. Within the past two decades, however, the use and content of career counseling have broadened in their application throughout the life span to populations experiencing an increasingly comprehensive array of career concerns. Thus, whereas traditional models of career counseling tend to focus on career exploration, job selection, clarification of life and career goals, and improvement in decision-making skills, more recent applications of career counseling tend to address problems that require a fusion of career and personal counseling. In the latter approaches, career counseling may address providing support to persons experiencing job stress, job loss, and major (often involuntary) career transitions; helping clients deal with work adjustment issues, such as coping with negative relations with a supervisor or coworkers; teaching clients to deal with anger management; restructuring work dysfunctions; modifying irrational career beliefs; or resolving conflicts between work and family roles.

Definitions of Career Counseling

As the problems clients bring to career counselors have expanded and become more complex, the definitions of career counseling have changed. These definitions have increasingly shifted from viewing career problems as rational, objective, and unaffected by emotional crises outside the workplace to examining the interaction of work-related problems with those of personal identity, family concerns, mental health, and related issues. Krumboltz (1993), for example, has stated emphatically that "career and personal counseling are inextricably intertwined. Career problems have a strong emotional component" (p. 143).

Brown and Brooks (1991, p. 5) have defined career counseling as follows:

> Career counseling is an interpersonal process designed to assist individuals with career development problems. Career development is that process of choosing, entering, adjusting to and advancing in an occupation. It is a life-long psychological process that interacts dynamically with other life roles. Career problems include but are not limited to career indecisions and undecidedness, work performance, stress and adjustment, incongruence of the person and work environment, and inadequate or unsatisfactory integration of life roles (e.g., parent, friend, citizen).

In essence, career counseling is used with individuals and with groups, represents a continuum of approaches tailored to the career concerns and needs of individual clients, and is likely to be part of a program of interventions that include career assessments, self-directed activities, assistance with skill development, and related functions.

Approaches to Career Counseling

Whatever the precise theoretical framework used, career counseling emphasizes maximum collaborative efforts between the counselor and the client to clarify the current situation of concern (e.g., needs for career planning, choice among possible options, an untenable work environment, work-family issues); clarify the client's personal role within the situation; identify action goals to be pursued in the career counseling process; identify information of relevance to the situation; develop insight about behavioral options available; and engage in problem solving to develop a plan of action. Within this general outline of a career counseling process, there are variations in what goals are emphasized, depending on individual differences and on theoretical orientations. For example, Brown and Brooks (1991) emphasize that many persons lack *cognitive clarity,* the ability to assess objectively one's own strengths and weaknesses and relate the assessment to environmental situations. In this view, persons who lack cognitive clarity also possess faulty logic systems that may result in what theorists describe as irrational beliefs, negative self-talk, or faulty private rules for decision making.

Beyond helping the client to achieve cognitive clarity or to confront faulty logic and negative cognitions about their career development, career counseling may include other approaches. Perhaps the most venerable is what has historically been called *trait and factor,* and more recently *person-environment fit* (Chartrand, 1991). Such an approach helps clients match individual traits to the performance requirements and work culture of particular jobs, occupations, or training. The intent is to increase the congruence between the client's abilities, interests, and values and the technical and psychosocial aspects of the job, occupation, or training option chosen (Holland, 1997). Embedded in such an approach is the goal of helping the client evaluate the probabilities or odds of gaining access to and being successful in different jobs, occupations, or educational opportunities. Such an approach is typically information and assessment driven. It often involves considerable analysis of the client's self-understanding, abilities, and preferences as an evaluative base to which to relate possible career options. Trait and factor (person-environment fit) approaches also are likely to help clients gain insight into the elasticity of their previous work experience with other jobs or occupations for which there is compatibility and fit.

Although there are also client-centered, psychodynamic, behavioral, cognitive, and constructivist approaches to career counseling, the final major approach to be discussed is the developmental approach. This approach emphasizes the client's coping with developmental tasks in the past and in the current choice situation. Such an analysis may focus on the client's readiness to cope with emerging roles and skill requirements, relinquishing roles that are no longer appropriate, and acquiring the attitudinal and behavioral elements of career adaptability required in the current life stage: planfulness, exploration, time perspective, assertiveness, flexibility, reality orientation, and so forth.

Evaluation of Career Counseling

A large number of studies have reported positive effects for career interventions on diverse career outcomes (Sexton, Whiston, Bleuer, & Walz, 1995). Within the positive effects found for career interventions in general, individual counseling has constantly been found to be the most effective intervention per unit of time involved (Oliver & Spokane, 1988; Sexton, Whiston, Bleuer, & Walz, 1997). Other researchers have concluded that although individual and group counseling and other techniques yield positive outcomes, they may be differentially effective for different types of clients (Herr & Cramer, 1996; Swanson, 1995).

CAREER DEVELOPMENT

Virtually all persons engage in multiple forms of career behavior throughout their life. Examples include preparing for a work role, choosing and entering a job or occupation, dealing with the dynamics of work adjustment, moving from one job to another, becoming unemployed, and making plans for retirement. Although there are similarities in how persons approach such work-related tasks, there are also significant variations between males and females, persons of different educational or socioeconomic levels, persons of different racial and ethnic backgrounds, and persons with physical and mental disabilities. The term *career development* describes the processes and factors that influence how individuals develop a personal identity in regard to work, and how their beliefs, values, interests, and aptitudes are reflected in the transition, induction, and adjustment to work.

Career Defined

In order to understand the term *career development,* it is useful to consider the term *career.* Jobs and occupations are part of one's career but are not synonymous with this concept. Jobs and occupations describe groups of tasks or work performances that occur within a workplace and that constitute paid positions that can be identified, applied for, and achieved. But the term *career* means more than work performance. Among the classic definitions of career is that of Super (1976):

> The course of events which constitutes a life; the sequence of occupations and other life roles which combine to express one's commitment to work in his or her total pattern of self-development. . . . Careers exist only as people pursue them. (p. 4)

In a more abstract sense, the term *career* "can refer to the individual's movement through time and space . . . [and] the intersection of individual biography and social structures" (Collin & Young, 2000, p. 3).

These definitions affirm that careers are unique to each person and created by what one chooses or does not choose. They are dynamic and unfold throughout life. They include not only jobs and occupations but prevocational concerns (school courses, job training) and postvocational concerns (retirement) as well as integration of other roles: family, community, and leisure.

Perspectives On Career Development

Career development can be understood as one of the many aspects of socialization that combine to create human development; in this case the focus is on occupational or work socialization. In psychological terms, the individual acquires motivation to act in certain ways related to his or her beliefs about personal self-efficacy to achieve in particular work domains, to the likelihood that certain valued outcomes will occur from some choices and not others, and to the salience of work to his or her personal identity. In sociological terms, however, individual career development is also a product of the constraints on and barriers to choices that individuals might prefer to make. Such constraints can occur because of limitations on individual choice that arise from political conditions or from economic circumstances. Sociological effects on choice also can be seen in family and cultural influences. Families with differing educational and socioeconomic backgrounds tend to reinforce different educational and occupational goals and belief systems related to career choice. Nations and cultural groups also differ in how particular types of education, work, or family roles are valued, and these perceptions tend to be internalized by group members and reflected in their choices.

Career development can be thought of in both structural and developmental terms (Herr & Cramer, 1996). The structure of career development refers to the elements that comprise concepts like career maturity, career adaptability, career planfulness, and person-job congruence (Holland, 1997). Career maturity, for example, in adolescence and career adaptability in adulthood tend to include five factors: planfulness or time perspective, exploration, information, decision making, and reality orientation. These five factors are structural components of career maturity, and each factor has its own structural sub-elements.

In addition to a structural approach to career development, there is also a developmental approach. In such an approach, the questions are different: Does career maturity change over time? Is behavior described as career mature at age 18 the same as career adaptability at age 25 or 45? What are the factors that influence career behavior at different life stages: childhood, adolescence, young adult, midcareer adult, older adult?

Further perspectives view career development as a lifestyle concept. In essence, the work roles that one implements throughout the life span are not independent of other life roles; indeed, they may be in conflict with them. For example, being a workaholic, a spouse, and a parent may be problematic if the amount of energy or time given to the work role is significantly out of balance with that given to these other life roles.

Theories of Career Development

The theories that offer explanations of career behavior are multidisciplinary. This is true in part because career identity and the socialization to work are such important aspects of human development in the developed nations of the world, and in part because the factors that influence career development take many forms. In capturing such a perspective, Super (1990) contended that

> The pioneers of career are people from four disciplines: differential psychologists interested in work and occupations, developmental psychologists interested in the "life course," sociologists focusing on occupational mobility as a function of social class, and personality theorists who view individuals as organizers of experience. (p. 197)

To these theorists of different aspects of career development, one can add the growing attention of political scientists, economists, and organizational theorists as persons concerned about career development. As a result of this disciplinary diversity focused on career behavior, some theory and research are primarily applied to job or occupational choice at a specific period in time (Holland, 1997), to the role or interests or other personal characteristics, to adjustment within a work setting, or to the decision-making process used by different persons. Some research is concerned with the structure of choice, work behavior, or career maturity within a particular life stage; other theories are concerned with how such structures change over time, the role of chance in career choice, and the continuities and discontinuities in career patterns throughout the life span (Super (1990). Some theories are more focused on the roots of career behavior in childhood and adolescence; other theories give greater attention to career behavior in middle and late adulthood. Growing attention is being given to the unique dimensions of career development in women and in different cultural groups and as it relates to mental health.

The changing nature of work (e.g., organizational downsizing, the pervasive use of advanced technology to increase productivity, the increasing use of part-time workers, international economic competition) and of career paths is providing new challenges to theories of career theory in the twenty-first century. Some theories in the twentieth century focused on career behavior that was linear and predictable within stable organizations. Such conditions are rapidly changing as workplaces use new means to remain competitive. The result is a widening diversity of career patterns and experiences, more frequent career transitions, and increased expectations that workers must become their own career managers. Such dynamics are not yet fully captured in career development theories.

CATHARSIS

Catharsis is a term used in aesthetics and the psychology of art with reference to spectator response, and in psychotherapy with reference to the release of repressed affect or psychic energy.

In ancient Greek, *katharsis* most commonly meant physical or spiritual purgation, ridding one of uncleanliness or guilt. Empedocles used it to speak of religious purification; Plato, to speak of purification of the soul by means of philosophy; and Hippocrates and his followers, to speak of the evacuation of morbid humors. But its most notable use in ancient times occurs in Aristotle's cryptic definition of tragedy as drama which "accomplishes through pity and fear the catharsis of such feelings" (*Poetics* 1449b). For literally centuries, philosophers, art theorists and critics, and psychologists have argued about what Aristotle meant, notably over whether the emotions are aroused in spectators or simply depicted in the drama and, if the former, whether they are purged, sublimated, or in some other way resolved. The term has been applied to a wide range of art forms and emotional responses or representations. According to philosopher Richard Kuhns (1998), "The spirit of catharis as an aesthetic principle"—though often not mentioned explicitly—"informs the work of [critics] I. A. Richards, F. R. Leavis, and Wolfgang Iser, and energizes the artistic achievements of many of our modern poets" such as Lawrence, Hardy, Eliot, Auden, and Stevens.

In psychoanalytic literature the term first appeared in *Studies on Hysteria* by Breuer and Freud, although both the naming and the therapeutic method initially associated with it are credited to Breuer (perhaps unjustly; Jacob Bernays, uncle to Freud's wife, believed that "catharsis" referred to a medical healing process, and his articulated view may well have influenced both Breuer and Freud). Breuer had apparently cured patients of hysterical symptoms by inducing them, under hypnosis, to relive or remember forgotten childhood events—often but not always traumatic—and the affects associated with them. Freud hypothesized that in such cases the mental or nervous energy that would have led to the original affect was diverted into hysterical symptoms, and that memories of the experiences were re-

pressed into the unconscious. When, under hypnosis, both the memory and the associated affect were brought into consciousness, the affect was thereby discharged and the symptom eliminated. The process of affective discharge was also called *abreaction.*

Although Freud soon replaced hypnosis with free association and enlarged his theory, he stated in "A Short Account of Psycho-Analysis" (1961) that the cathartic method was both the precursor and the ongoing nucleus of psychoanalysis. Catharsis thus remains a basic concept, even though the term itself has lost favor among psychoanalysts. In its psychoanalytic context—referring to the release of repressed ideas and affects—it has also been an important and fruitful concept in theorizing about spectator responses to works of art by thinkers within the psychoanalytic tradition (such as Kris), outside it (such as Vygotsky), and partly in and partly out (such as Wollheim).

In contemporary psychotherapy outside the psychoanalytic tradition, *catharsis* is often defined much more loosely as referring in a general way to the therapeutic release of emotions or tensions, including some that might be conscious or related to conscious experiences. A central concept in psychodrama, catharsis is also a major aspect of Gestalt and primal therapies and of most brief and crisis-oriented therapies. Sometimes it is called "talking out," "acting out," or "ventilation." In implosive therapy there is a deliberate attempt to elicit strong emotions in order to bring about cathartic release of tension.

Controversy persists concerning the effectiveness of catharsis as merely emotional release rather than its more fundamental role in a psychotherapeutic process of reintegration.

CENTRAL LIMIT THEOREM

The central limit theorem concerns the distribution of a linear composite. Y is a linear composite of a set of variables ($X1, X2, X3$, etc.) if $Y = a1\,X1 + a2\,X2 + a3\,X3 + \ldots$, where the a's are weights. For example, if Y equals $3X1 + 4X2$, then $a1$ equals 3 and $a2$ equals 4. The central limit theorem states that the shape of the distribution of Y becomes more and more like the normal distribution as the number of variables included in the composite increases. Specifically, the central limit theorem states that Y is asymptotically normal as the number of composited variables approaches infinity. The central limit theorem is one of the principal reasons that psychologists and statisticians make regular use of the normal distribution.

Table 1. Distribution of X

Value of X	Probability of X
0	.50
1	.50

Table 2. Distribution of Y

Value of Y	Probability of Y
0	.001
1	.010
2	.044
3	.117
4	.205
5	.246
6	.205
7	.117
8	.044
9	.010
10	.001

Notice that the theorem does not require that the variables in the composite be normally distributed. Y is asymptotically normal even when the composited variables have very nonnormal distributions. Perhaps this is most easily illustrated by compositing a set of coin tosses. Imagine tossing a fair (unbiased) coin one time, recording 0 for a tail and 1 for a head. This experiment has two possible outcomes, each equally likely. If we call the experiment's outcome X, it can be concluded that $P(X = 0) = 0.5$ and $P(X = 1) = 0.5$. The distribution of X is given in Table 1.

Repeat this simple experiment 10 times, generating values for $X1, X2, X3 \ldots X10$. Each of the X's has the same distribution. It is possible to create a new variable that is a linear composite of the X's. Let $Y = X1 + X2 + X3 + \ldots + X10$. Y is the number of heads in 10 tosses of a fair coin, and the distribution of Y is given in Table 2. Notice that with only 10 variables in our composite, Y resembles the normal distribution; probabilities are highest in the middle of the distribution and gradually decrease for more extreme scores. If the coin were tossed 1,000 times and the outcomes were summed, the distribution of this sum would be almost indistinguishable from the normal distribution.

The central limit theorem frequently is introduced as a special case, to describe the distribution of the sample mean. The sample mean is a linear composite of the scores in the sample, with each score weighted by $1/N$, where N is the sample size. If N is large enough, the distribution of the

sample mean will be normal, so the normal distribution can be used to build confidence interval estimates of the population mean and to test hypotheses concerning the sample mean. Researchers generally assume the sample mean has a normal distribution if N is at least 30, but how quickly the distribution assumes the normal shape depends on how normal the X's are. If the X scores are normally distributed, their mean always will be normally distributed. If the X scores are very nonnormal, N may have to be larger than 30 for the distribution to be normal.

The central limit theorem also can explain why many physical measurements are normally distributed. Human heights and weights are determined by many factors, probably including hundreds of genes and thousands of variables related to nutritional and psychological history. Heights or weights can be thought of as composite of thousands of variables, so they should be normally distributed. Many psychological traits, such as intelligence, also are normally distributed, probably because they are influenced by thousands of genes and prenatal and postnatal events. Deviations from normality suggest the heavy influence of one event that overrides the linear composite. For example, people who are so extremely short that their presence is not consistent with the normal distribution may have heights determined by a pituitary problem. Their heights are not influenced by the genes and events that under other circumstances would have made them taller. Similarly, people with extremely low intelligence may have a rare genetic defect or may have been subject to some trauma that damaged the central nervous system.

CENTRAL NERVOUS SYSTEM

The central nervous system (CNS) refers to the portion of the nervous system that lies within the skull and spinal column and receives nervous impulses from sense receptors throughout the organism, regulates bodily processes, and organizes and directs behavior. Anatomically, the CNS comprises the brain and spinal cord, which float within the cranial cavity of the skull and the vertebral canal of the spinal column in a liquid matrix called *cerebrospinal fluid,* which also fills their hollows and serves as a protective cushion against damage. CNS tissue is further protected by three enfolding membranes called the *meninges.* The outer and toughest, the dura mater, attaches to skull and spine, encasing the spongy arachnoid membrane within which the cerebrospinal fluid circulates. The soft pia mater is contiguous with the outer layer of brain and cord.

The basic structural unit of nervous tissue is the nerve cell or neuron, a specialized body cell of elongated shape (from a few microns to several feet in length), whose enhanced reactivity and conductivity permit it to propagate or conduct an electrical impulse along its length and to chemically stimulate adjacent neurons to do likewise at specialized junctions called *synapses.* The nervous system is made up of billions of neurons, which interconnect every part of the organism to monitor and regulate it. Receptor neurons lead like the twigs of a tree inward to branches and thence to great trunks, called *nerves,* which enter the CNS and ascend into the brain. There, effector neurons originate and descend to exit the CNS as nerves branching repeatedly out to regulate all muscle tissue and therefore all bodily activity. Twelve bilateral pairs of cranial nerves enter the brain directly. The cord is the origin of 31 bilateral pairs of spinal nerves, which exit the CNS through openings between adjacent vertebrae. Each spinal nerve contains both entering receptor fibers and departing effector fibers. The nerve divides on reaching the cord, with sensory fibers entering on the back and motor fibers exiting on the front.

The spinal cord is thus a great pathway for ascending and descending nerve tracts, but connectedness is a property of the CNS, within which a third type of neuron, the interneuron, is found. Interneurons connect effector and receptor neurons, and by repeated branchings of their tips may synapse at either end with many hundreds of other neurons. The functional unit of the nervous system is the reflex arc, which so links receptor and effector neurons that a stimulus at a sense receptor capable of causing its nerve to conduct will automatically trigger an effector neuron to produce a response in a muscle or gland. Some reflexes are extremely simple, but most are not. The CNS is hierarchically organized, with higher centers being stimulated by and acting upon lower centers, so that progressively more complex reflexes are organized progressively higher in the CNS. Certain muscle stretch reflexes operate spinally for the most part. Respiratory reflexes are largely centered in the brain stem, the part of the brain that is contiguous to the spinal cord. Homeostatic reactions depend upon reflexes organized higher yet, in the hypothalamus, which may give rise to motivational states such as hunger and thirst. It is thought that by means of progressively more complex reflexes (some inborn, but most acquired through learning) all functions of the CNS are conducted, including the higher mental functions, the seat of which is the brain. The CNS is also symmetrically organized. Midline structures like the cord have two symmetrical halves. Other structures are duplicated, such as the two cerebral hemispheres. Most fibers cross the midline (e.g., the left brain controls the right hand).

The brain is an organ of unparalleled complexity of parts and function, a reality that may be obscured by summary description. A great deal has nevertheless been learned about the pathways that are followed by ascending and descending nerve tracts. Much of the CNS is white matter, the

encased processes or extensions of nerve cells, bundles of which indicate pathways called tracts. The nerve bodies are not encased and are present as gray matter, clusters of which indicate centers of activity called *nuclei.* Evolutionary influences have given characteristic shapes to the complex arrangements of neurons in the CNS, permitting to be named and located on charts or in living tissue.

The gross anatomy of the brain, in greatly oversimplified summary, may be divided into three regions: (1) the brain stem, the parts of which (medulla, pons, mesencephalon) contain the nuclei of the brain stem reticular formation, which is vital in consciousness and the level of arousal of the brain above; (2) the cerebellum, a center for the smooth regulation of motor behavior; and (3) the cerebrum, which is of greatest interest to psychology for its organizing role in the higher mental functions and emotion. Between brain stem and cerebrum are the thalamus and hypothalamus, which some authorities class with the brain stem, some with the cerebrum. Thalamic nuclei largely integrate and relay sensory impulses upward to the cerebrum. Hypothalamic nuclei, however, are vital in the regulation of homeostatic reactions and in integrating the reflexes of the nuclei of the limbic system, structures embedded deep within the cerebrum that give rise to emotional experience and expression.

The cerebrum's deeply fissured gray outer surface, the hemispheres of its cerebral cortex, is the terminus of sensory processes and the origin of motor processes. Much of this area is given over to association areas of interneurons, whose complex interconnections give rise to memory, speech, purposive behavior, and, generally, the higher mental functions.

The pathways, relays, and sensory and motor areas of the brain have been mapped by largely physical and physiological methods. But the nature of the higher mental processes of humans remains elusive because they cannot be charted thus. As J. Minckler observed, the structure and function of nervous tissue are so intertwined that they must be studied together. At some levels of the CNS, the appropriate units of function are physiological. Other levels are best studied through discrete behaviors. Still more complex functions of brain, however, require the scrutiny of complex patterns or styles of behavior, and the highest levels of brain function shade into issues of intelligence, logic, purpose, and consciousness, themselves as little understood as the brain.

The study of the CNS in humans is thus the study of brain-behavior and brain-mind relationships, a field in which psychology is heavily involved. That there is a relationship between brain and mind is well established and has been observed for a very long time. C. J. Golden noted that Pythagoras, in 500 B.C., linked brain and human reasoning. In the second century A.D., Galen of Pergamum observed the effects on consciousness of brain injury in gladiators and described animals rendered senseless by pressure on their brains.

Galen was incorrect in attributing mental processes to the fluid-filled hollows of the brain, a view which nevertheless endured until the Renaissance. Modern concepts regarding brain functions did not begin to develop until the 1800s. This delay resulted from vitalistic and imprecise views of both brain and mind, and it endured until a more scientific and reductionistic view of both brain and behavior emerged. Rarnón y Cajal forwarded neuron theory in the late 1800s and received a Nobel Prize in physiology in 1906, the same year that C. S. Sherrington, who developed the concept of the reflex arc, published on integrative mechanisms of the nervous system. Galton's work with the behavioral measurement of individual differences contributed greatly to the emerging science of psychometrics or mental measurement. In the early 1900s, J. B. Watson moved psychology toward the study of behavior rather than mental states. He and B. F. Skinner both contributed to a science and technology of behavior that has meshed well with biology in permitting brain behavior studies. But the complexities of mind or behavior and brain are such that the more we learn, the more there remains to be learned. In 1974, G. Sommerhoff put it thus: "The peculiar fascination of the brain lies in the fact that there is probably no other object of scientific enquiry about which we know so much and yet understand so little."

At the heart of the problem lies the fact that the nervous system, so simple in basic elements, is so complex in arrangements. As Hubbard observed in 1975, it is easy to imagine neuronal arrangements capable of causing muscles to contract or glands to empty, but it is difficult to imagine such arrangements permitting the aging Beethoven to compose works he could no longer hear. The sheer complexity of interconnections, which could well permit such complex behaviors, virtually defies understanding. Some five million neurons, for example, may lie beneath a single square centimeter of brain surface, each of which synapses with perhaps 600 other neurons. Virtually the entire depth and surface of the brain may be involved in any given behavior.

To be understood, the brain (and possibly all the CNS) must be understood as a whole. Yet owing to limits in theory, knowledge, and perhaps capacity, we must approach the whole through study of the parts, viewed at many levels and from many perspectives. Full understanding of the CNS thus lies beyond any one discipline. Psychology, however, contributes in many ways to the expanding interdisciplinary study of the CNS, called *neuroscience.* Psychologists have put forward or contributed to models of mind compatible with known facts of brain function and have helped develop new models of neural function drawing on and contributing to computer modeling. They have also used neuroscientific findings to develop broad models of human behavior. Psychologists also commonly contribute directly to knowledge of brain-behavior relationships through experimental and clinical neuropsychology.

Experimental neuropsychologists have long studied such things as the behavioral derangements caused by

known lesions and other disturbances of CNS tissue in animals. Clinical neuropsychologists have increasingly used qualitative and quantitative aspects of behavior on special tasks to deduce or infer the probable locus and nature of brain tissue impairment in individuals. The accuracy of such assessments reached very substantial levels by the 1970s, and behavioral mappings of the strengths and deficits of brain-injured individuals contribute significantly to current treatment and rehabilitation efforts.

Ongoing developments in knowledge and methodology continue to require new connections among the disciplines comprising the evolving field of neuroscience.

CENTRAL NERVOUS SYSTEM DISORDERS

The central nervous system (CNS) is composed of the brain and the spinal cord. The spinal cord controls movement and feeling of body regions located below the brain. The brain also plays a role in movement and feeling. However, the brain's role is more complex than that of the spinal cord, and the brain controls complex psychological processes as well (e.g., attention, perception, motivation, emotion, language, cognition, and purposeful behaviors). When certain parts of the brain are damaged, specific functions may be lost. The type and extent of functional loss depend upon the age of the individual, the location of the brain damage, its etiology, and the amount of brain tissue that is compromised. For example, damage to a strip of cortex in the posterior part of the frontal lobes controlling movement of parts of the body will result in paralysis of those body parts. Lesions within relay stations along the visual sensory system—from the optic nerves to the occipital lobes—will result in visual field defects such as scotomas (blind spots). Lesions deep in the hypothalamus may produce hunger, uncontrolled eating, and obesity. Destruction of areas involved in arousal may result in a permanent comatose state. Finally, damage early in life can be less devastating than analogous damage in late adulthood.

Disorders of the CNS usually are classified according to lesion location (e.g., abnormalities occurring after frontal lobe damage) or according to etiology, symptomatology, and functional loss (e.g., amnesia). The following discussion focuses on two exemplars of CNS disorders. The first, frontal system disorders, exemplifies possible consequences of damage to the anterior regions of the frontal lobes (Stuss & Knight, 2002). The second, amnesia after long-term alcoholism (Oscar-Berman, 2000), exemplifies a disorder recognized by abnormalities of memory, especially memory for recent events (anterograde amnesia). Keep in mind that the distinction between structure and function is not a mutually exclusive one. The brain has many highly interconnected parts, and when one part is damaged, other parts will be affected as well. Similarly, behavioral abnormalities are complex; they involve a broad spectrum of perceptual and cognitive deficits that may be integral to the presenting symptoms of many disorders of the CNS (Armengol & Jamieson, 2001; Lezak, 1995; Mesulam, 2000; Spreen & Strauss, 1998).

Frontal System Dysfunction

The frontal lobes are connected with all of the other lobes of the brain, and they receive and send fibers to numerous subcortical structures as well (Fuster, 1997). Control of motor function takes place in the posterior region of the frontal lobes. The anterior region of the frontal lobes (prefrontal cortex) plays a kind of executive regulatory role within the CNS, inhibiting the occurrence of unnecessary or unwanted behaviors. Disruptions of normal inhibitory functions of frontal lobe neuronal networks often will have the interesting effect of releasing previously inhibited behaviors from frontal control. The resultant aberrant conduct of a frontal patient may be due to the freely unregulated functioning of the released brain regions (disinhibition).

Early evidence for a role of the frontal lobes in supporting the ability to inhibit impulsivity came from the 1868 report of a physician on his patient Phineas Gage. Gage, a railway workman, survived an explosion that blasted an iron bar (about four feet long and an inch wide) through his frontal lobes. After he recovered from the accident, Gage's personality changed. He became irascible, impatient, impulsive, unruly, and inappropriate. The damage had mostly been in the orbital frontal region of Gage's frontal lobes (Mesulam, 2000; Stuss & Knight, 2002).

Damage to frontal brain systems occurs in a number of CNS disorders, including stroke, brain tumors, dementing diseases (e.g., Alzheimer's), and head trauma (Lichter & Cummings, 2001). Patients with bilateral frontal disorders

often display a pull to nearby objects (e.g., grabbing at doorknobs) as well as a remarkable tendency to imitate the actions of people nearby (echopraxia). The behaviors of a frontal patient appear not to be based on rational decisions; rather, some responses are under the control of salient objects around them (i.e., objects that capture the attention). In other words, the patient's behaviors are environmentally driven rather than personally chosen. Such behaviors may extend to otherwise embarrassing gestures such as urinating in public or chewing paper.

Alcohol-Induced Persisting Amnesiic Disorder (Korsakoff's Syndrome)

Amnesia, especially *anterograde amnesia,* or memory loss for recent events, is an intriguing but serious disorder. When amnesia occurs as a consequence of long-term alcoholism, it is referred to as *alcoholic Korsakoff's syndrome.* Patients with Korsakoff's syndrome are permanently unable to remember new information for more than a few seconds. However, memories that were formed prior to the onset of alcohol-related brain damage are relatively well preserved. Because new events are forgotten a few seconds after they occur, virtually nothing new is learned, and the patient with Korsakoff's syndrome lives in the past.

The critical brain lesions of alcoholic Korsakoff's syndrome are thought to include the mammillary bodies of the hypothalamus and/or medial thalamic nuclei (Oscar-Berman & Evert, 1997). Damage to these or to other regions of the brain (hippocampus, fornix, anterior thalamus) has long been associated with memory impairments (Mesulam, 2000). The impairments include severe anterograde amnesia for recent events, and some retrograde amnesia (i.e., loss of memory for events that happened prior to the appearance of obvious symptomatology). Damage to basal forebrain structures (important in the production of neurotransmitters, which are needed for normal memory functions) may also be involved.

Although anterograde amnesia is the most obvious presenting symptom in Korsakoff patients, these individuals have other cognitive impairments as well. Like patients with bilateral prefrontal cortical lesions, Korsakoff patients are abnormally sensitive to distractions (proactive interference). This sensitivity may be due to alcoholism-related prefrontal dysfunction, which impairs the ability to counteract the effects of cognitive interruptions. In addition to their memory problems and their sensitivity to interference, Korsakoff patients also tend to repeat unnecessary behaviors (perseverative responding) and have restricted attention, retarded perceptual processing abilities, and decreased sensitivity to reward contingencies (Oscar-Berman & Evert, 1997). These additional abnormalities reflect widespread cerebral atrophy accompanying sustained alcohol abuse. Thus, consideration should be given to sensory and cognitive deficits that may be integral to the disease process caused by chronic alcoholism.

CENTRAL TENDENCY MEASURES

We often wish to provide summary numbers that best describe a set or distribution of scores. These include measures of *location,* which indicate a typical or average value for the scores; measures of *dispersion,* which indicate how spread out the scores are; and measures that describe the *shape* of the distribution.

A measure of central tendency is a measure of location; the goal is to provide a single number that best describes the values of a set of scores. The terms *measure of central tendency* and *average* are often used interchangeably, although some authors use *average* only to refer the arithmetic mean. Although there are many measures of central tendency, those most commonly encountered are the mode, median, and mean.

Given a set of scores, the *mode* is simply the score that

occurs most often. If scores are grouped into classes, the mode is considered to be the midpoint of the class that contains the largest number of scores. The mode is not a very useful summary measure because it does not take into account scores that do not have the modal value; also, there may be two or more values that occur with high frequency.

The *median* is the middle score of a distribution. If the scores are ordered from smallest to largest, the median is the middle score. If there are an even number of scores, the median is considered to be halfway between the two middle scores. For example, given sets of scores A (6, 8, 4, 9, 11) and B (6, 8, 4, 9, 11, 14), the median of A is 8 and of B is 8.5. For grouped data, the median is taken be the 50th percentile point—the value below which 50 percent of the scores fall. Because the median is insensitive to the values of scores at the extremes of the distribution, it is useful for characterizing distributions that include outliers, extreme scores that are quite different from the scores in the center of the distribution. The median for (6, 8, 4, 9, 11) is the same as for (6, 8, 4, 9, 11944).

The *arithmetic mean* is the most commonly encountered measure of central tendency. It is obtained by adding up all of the scores in the set and dividing by the number of scores. The mean depends on all the scores in the set; as a result, the mean is sensitive to extreme values. Although the medians for the sets (6, 8, 4, 9, 11) and (6, 8, 4, 9, 11944) are the same, 8, the means are 7.6 and 2394.2, respectively. Here the median does a better job of characterizing the typical value of the scores.

It is useful to think of the mean of a distribution of scores as the balance point of the distribution. Imagine that scores are represented by weights placed on a balance beam at locations corresponding to their values. Then the location of the balance point of the set of scores corresponds to the value of the mean. For example, suppose that equal weights are placed at locations 4, 6, 8, 9, and 11 units from the left edge of a weightless, rigid beam; then, if the beam is placed on a fulcrum located 7.6 units from the left edge the beam, it will balance. Another way of thinking about this is that if we find the deviation of each score from the mean, then add up all these deviations, they will sum to zero.

Another useful characteristic of the mean is that it is the value that minimizes the *sum of squared deviations.* That is, if we find the deviation of each score from a value M, square each deviation, then add all these squared deviations together, the sum is smaller if M is the mean than if it is for other value. The median is the value that minimizes the sum of the *absolute values* of the deviations.

For a symmetrical distribution of scores, the mean and median will have similar values. If the distribution of scores is skewed to the right (that is, if the distribution is asymmetrical, with a short tail on the left side of center and a longer tail on the right), the mean will be larger than the median. If the distribution is skewed to the left, so that it has a longer tail on the left side, the mean will be smaller than the median.

We are very often interested in estimating the mean of a population of scores on the basis of samples of scores selected from the population. We can use a measure of central tendency of the sample, such as the sample mean or median, as an estimator of the population mean. If we take a number of samples of the same size, these sample means and medians will vary from sample to sample because of the variability in the scores selected to be in each sample. If the population is bell-shaped (i.e., if the scores are distributed like the normal distribution), it can be shown that the sample mean is a more efficient estimator than the sample median. The mean is more efficient in the sense that the means of samples can be shown to cluster more closely around the population mean than the sample medians, and so they tend to be better estimates of the population mean. If, on the other hand, the population is asymmetric or heavy-tailed (i.e., it tends to contain extreme scores), the sample mean may not be as good an estimator as the sample median or certain kinds of trimmed means (that is, sample means obtained after discarding some of the smaller and larger scores in the sample).

CEREBELLUM

The cerebellum is one of the two largest structures in the mammalian brain, and, like the cerebum, it has two hemispheres. The cerebellum receives a full range of sensory information directly from the peripheral sensors (including auditory and visual). It also receives motor and sensory information from the cerebral cortex. It is involved with the learning-based control and elaboration of reflex homeostatic responses at the brain stem and spinal cord level and may operate in parallel with the cerebral cortex in controlling motor performance. However, the cerebellar system is thought to be particularly important for the control of frequently executed or rehearsed movements that become automatized and are performed without conscious effort.

The cerebellum is considered to be able to represent and process both sensory and motor information and to do so in a unified manner, that is, as a *sensorimotor system.* It is capable of rapid information processing and real-time regulation of coordinated sensorimotor activity. On the basis of its microstructural and functional characteristics it is con-

sidered that the cerebellum is essentially a *parallel distributed* or *connectionist* type of system that represents and processes information in a probabilistic manner. As a consequence of its parallel distributed amodal representation and processing, the cerebellum is considered to be an analog or holistic type of system and to facilitate associative storage. However, another consequence is that it lacks potential for highly specialized analysis of sensory-specific information: That is, it is a relatively low-discrimination system.

Based on parallel distributed representation and processing models of cerebellar function, a number of other processing or computational features have been inferred. The cerebellum may detect and respond to patterns or features, which may be determined partly on the basis of the relative frequency with which they occur. Parallel processing facilitates the automatic statistical revelation and statistical evaluation of features that are to varying extents common to a number of information inputs or experiences. In this respect the cerebellum may be considered to separate "figure" from "ground" and function like a *Gestalt system.* When a significant part of a frequently occurring feature or pattern is received as an input, the cerebellar system will recognize that part as though it is the whole, thus in effect completing or generating the expected pattern. This phenomenon may be involved in nonverbal analogical reasoning.

In a similar manner, when part of a familiar sequence is received as an input, the cerebellar system will respond so as to complete the expected temporal pattern. This is a kind of predictive mechanism and facilitates anticipatory responses based on the learned response sequences (sensorimotor schemata). These processing characteristics could facilitate associative learning in the form of classical conditioning or operant conditioning and would allow for sensory stimuli to act as retrieval cues for stored information concerning the response that past experience suggests is the most probably beneficial. The cued or released sensorimotor information would automatically, through its motor component, involve a behavioral response. Such responses generated by the cerebellum would appear to be released in an all-or-none fashion—that is, as wholes. It is thought that the cerebellum does not allow for the erasure of recorded information. The only way that information can in effect be forgotten is by functionally overlaying the information to be forgotten with the information to be remembered in preference (similar to the behaviorist notion of extinction).

Over the years there has been a steady accumulation of evidence that the cerebellum is critically involved in the classical conditioning of simple motor responses. Thompson et al. (1997) have shown that the essential memory traces for a range of classical conditioning responses are formed in, and reside in, the cerebellum. It is now generally assumed that the cerebellum plays a major role in sensorimotor learning. This form of learning is evident at the earliest stage in human cognitive development and is typified by the developmental concepts of enactive representation (Bruner) and sensorimotor intelligence (Piaget). Given this, one might expect that the cerebellum would be involved in cognitive processing at a fundamental level.

A range of research (including Tomographic regional cerebral blood flow [rCBF], regional cerebral metabolic rate [rCMR], and position emission tomography [PET] studies) indicates that in humans the cerebellum contributes to various cognitive process. It appears to be involved with verbal processing, including speech, writing, and reading, not only in the direct motor expression of these skills, but also in the mental simulation and rehearsal of these skills, and in related nonmotor aspects such as word association. It also appears to be involved with visual processing, including imagined motor expression (tennis movements, writing, speech), visual discrimination, mental rotation of simple drawings, and visuospatial organization tasks. Studies have indicated that cerebellum contributes to IQ, mainly visual IQ (performance scale IQ test ability on the Wechsler Adult Intelligence Scale, in particular, picture completion, picture arrangement, and object assembly). Other higher-order cognitive processes in which the cerebellum has been implicated include the skilled manipulation of symbols, conceptual reasoning, and complex planning activities. In summary, several publications have suggested that the cerebellum is involved in a range of cognitive processes, including what has been described as "pure mental activity" and "pure cognitive activity." Data suggest that for verbal processing, including writing and spoken language (verbal working memory and non-motor processing of words such as semantic association tasks), it is the right cerebellar hemisphere that is most involved. The lateralization to the right cerebellar hemisphere is consistent with observations that each cerebellar hemisphere is anatomically and functionally related to the contralateral (in this case the left, language-dominant) cerebral hemisphere. In contrast, complex cognitive spatial operations and visual reasoning are associated with processing in the left cerebellar hemisphere. The cerebellum and cerebrum may be considered complementary and facilitate optimal cognitive performance by the brain as a whole.

In the execution of motor processes, it is considered that the cerebellum does not operate at the level of normal consciousness but, relative to the cerebrum, operates at an unconscious level. Similarly, it is considered that its sensory processing operates not at a conscious level but rather as an unconscious mind's eye. Cerebellar contributions to cognitive processing skills could therefore constitute part of what has been called the "cognitive unconscious."

The cerebellum is one of two cortical subsystems capable of cognitive processing of information from the environment and of controlling the behavior of the organism; in evolutionary terms it is, in part, the earliest to develop and therefore, in part, relates to later stages of cognitive development; it is particularly associated with unconscious control and cognition. In information representation and processing terms it may be described as a parallel processing

sensorimotor subsystem of relatively low level of discrimination, and from this perspective it is complementary to the cerebrum.

CEREBRAL LOCALIZATION

The theory that different parts of the brain subserve different functions is known as *localization theory.* It is consistent with the basic biological principle that structures that do not look alike should have different functions. Localization of function is the theoretical backbone of modern neuropsychology, neurology, and related disciplines, all of which attempt to correlate specific behaviors with specific brain parts.

In the history of the brain sciences, it is possible to conceive of the theory of localization as being applied to the whole and then to increasingly smaller parts (Finger, 1994). At first the question seemed to be "Why is the brain special and how is it different from other organs, such as the heart?" This was an important question in classical and Hellenistic Greece, where opinions were divided. Aristotle (384–322 B.C.), the greatest of the Greek naturalist philosophers, believed that the heart was the seat of sensory and cognitive functions and that the brain simply tempered "the heat and seething" of the heart. In this regard, he was consistent with the archaic Greeks and the Egyptians. In contrast, Plato (c. 429–348 B.C.), in agreement with the thoughts of the Hippocratic physicians, believed that intellect belonged not in the heart but in the head.

During the Roman period, Galen (130–200 A.D.) reasoned that the seat of the highest soul, and hence the seat of intellect, had to be the brain itself. He listed imagination, cognition, and memory as basic components of intellect, but in his surviving writings he did not localize these functions in different parts of the brain (Finger, 2000). What he did write was that the soft front of the brain is likely to be sensory (better able to receive impressions), whereas the harder back (cerebellar) region is likely to be motor.

The church fathers of the fourth and fifth centuries A.D. went one step further when they localized imagination, intellect, and memory in the different hollow ventricles of the brain. One of the earliest advocates of ventricular localization was Nemesius (fl. 390 A.D.), a bishop in Syria. He localized perception in the two lateral ventricles, cognition in the middle ventricle, and memory in the posterior ventricle. This early localization theory was also embraced by St. Augustine (354–430), and it was broadly accepted in its general form for more than 1,000 years (i.e., some writers varied the ventricles that were associated with these particular functions).

During the Renaissance, as scientists returned to dissection and experimentation, observation began to replace conjecture. Leonardo Da Vinci (1472–1519) made molds of the ventricles to reveal their shape, and Andreas Vesalius (1514–1564) showed that the ventricles vary little across mammals. Consequently, the idea of ventricular localization slowly gave way, and increased attention began to be given to differences in the size and makeup of the brain itself.

The freer thinking and questioning of the Renaissance set the stage for Thomas Willis (1621–1675), an Oxford physician, who published his *Cerebri Anatome* in 1664 (Finger, 2000). Willis proposed that the corpus striatum, which he defined as all white matter between the basal ganglia and the cortex, plays a role in sensation and muscle movement, and that the cerebral cortex controls memory and the will. The cerebellum (which was broadly defined to include some pons and midbrain) was thought to regulate involuntary, smooth motor functions, such as breathing. This division of the brain into working parts, based partly on comparative anatomy, partly on clinical material, and partly on speculative theories, helped to change thinking about the functional organization of the brain.

The opening decades of the 1800s proved to be an especially important time in the history of localization theory. First, Julien Jean César Legallois (1770–1840) provided the first accepted localization within a region of the brain. In 1812, he pinpointed the area responsible for respiration within the medulla. In addition, the seeds were planted for modern cortical localization theory when Franz Gall (1757–1828) presented his theory of organology (his assistant Spurzheim preferred the word *phrenology*) at about the same time (Finger, 1994, 2000; Young, 1970). Gall maintained that different areas of the cerebral cortex govern different mental faculties and that cranial features reflect the development of these different organs of mind. Among other things, Gall was convinced that humanity's highest functions (e.g., speech) belong in the front of the cerebrum.

The theories of Gall and his followers stimulated great debate. Some scientists thought they had merit, others found them absurd, and still others believed that cortical localization made sense but that cranioscopy was a dead end that must be replaced by careful neurological examinations. The latter position was advocated by Jean-Baptiste Bouillaud (1794–1881). This Frenchman began to localize speech in the anterior lobes in 1825, and he then spent decades collecting clinical and autopsy material supportive of speech localization.

The debates over cortical localization continued to heat

up until 1861, when Paul Broca (1824–1880) presented his celebrated case of M. Leborgne ("Tan") in Paris (Finger, 2000). His sickly, hospitalized patient had lost his capacity for articulate language (among other things), and an autopsy revealed a lesion involving the third frontal convolution of the left hemisphere. Broca's localization of a center for articulate language toward the back of the frontal lobes went further than Bouillaud's broader anterior lobe idea, and it became the first cortical localization to receive broad acceptance.

In 1865, Broca published another landmark paper. As his collection of cases continued to grow, he had recognized that the left hemisphere must be special for speech. Left hemispheric dominance for speech was something that Marc Dax (1770–1837) had written about in 1836. Unfortunately, Dax failed to make his findings public in his lifetime. Thanks to his son Gustave, however, his report on more than 40 cases also appeared in print in 1865, the same year as Broca's own paper on the subject (Finger & Roe, 1996; Joynt & Benton, 1964).

In 1870, Gustav Fritsch (1838–1927) and Eduard Hitzig (1838–1907) discovered the motor cortex of the dog, first by stimulation and then by ablation (Finger, 2000). This was a significant accomplishment, because it showed that cortical localization could be studied under controlled conditions in laboratory animals. In the wake of this paper, lesion studies were conducted to localize sensory functions, such as vision and hearing, as well as higher intellectual functions, such as attention and memory. The leader of the new localization movement was David Ferrier (1843–1928), a Scottish physiologist-physician who moved to London. His most influential book, *The Functions of the Brain,* was first published in 1876 (Finger, 2000). Three other early contributors to the cortical localization movement were Hermann Munk (1839–1912), a German, and Victor Horsley (1857–1916) and Edward Schäfer (1850–1935), two Englishmen.

The success of localization theory was not, however, based solely on pathological (brain lesion) material—it also received good support from other sources. In 1875, Richard Caton (1842–1926) of Liverpool reported that cortical electrical activity varied in accord with Ferrier's maps when animals chewed, looked at flashing lights, and so forth. In addition, Paul Flechsig (1847–1929) showed that different cortical areas become myelinated at different times, a finding he correlated with the gradual attainment of different functions. Cytoarchitectonic studies of the cerebral cortex, such as those of Korbinian Brodmann (1868–1918), represented another significant source of support for localization theory.

Today, efforts continue to divide the brain into smaller functional units, albeit with positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) scans and other sophisticated tools that could not even have been imagined when Broca was living. In this regard, localization theory is alive and well. However, so is the moderate holistic notion, which holds that the brain is not a collection of independent functional parts but a remarkably unified organ made up of interacting specialized parts that are laid down by the genes and shaped by experience.

CEREBRUM

The cerebrum is the larger of the two cortical subsystems in the mammalian brain, the other, smaller subsystem being the cerebellum. Most of the cerebrum is the cortex, which has two hemispheres, each containing four lobes (frontal, parietal, temporal, and occipital). As a whole, the cerebral cortex is the most recent brain structure to evolve. It normally operates as the highest-level subsystem within the brain and is associated with conscious and volitional control of behavior.

Most basically, the cerebrum is involved with the control and elaboration of reflex homeostatic responses at the brain stem and spinal cord level. This control may be directly from the cerebrum to the brain stem and spinal system, or it may be indirectly through control of cerebellar output. The cerebrum is particularly involved with motor control that is under conscious volition and with discrete and precisely refined movement. These voluntary movements will be controlled by the cerebrum and will rely on feedback to the cerebrum from sensory organs. However, after repeated execution through habit, or through deliberate practice, control of the motor output sequence may be carried out by the cerebellum and may then be performed more quickly and more automatically with less conscious effort. Conscious practice may be seen as subprogramming of the cerebellum by the cerebrum. Such practiced action sequences may thereafter be switched on by the cerebrum and then released automatically from the cerebellum without further involving the cerebrum.

Sensory input direct from the peripheral sensors first reaches the cerebral cortex in the various unimodal pri-

mary areas. The most basic cerebrocortical processing is therefore concerned with sensory processing limited to a single modality. Within the cerebral cortex there is directionality of information flow from primary sensory areas, through secondary association areas and tertiary amodal regions that integrate information, and eventually to output areas that control motor function. Anatomic, physiological, and behavioral studies have all emphasized that there is a clear *sequential processing* built into cerebrocortical organization. The unimodal primary reception areas of the cerebral cortex result in a process of information abstraction by sensory modality. In addition, the cerebral cortex can selectively control its own input via the thalamus, and most of this control is inhibitory (i.e., of a filtering kind). Through its ability to abstract information (facilitated partly by unimodal primary representation and partly by input filtering) the cerebral cortex is thought to provide the brain with a system for high-level discrimination and for the analytical and abstract processing that is characteristic of logical thought or formal operational reasoning.

Evolution of the cerebral cortex, with its cerebrocortical primary sensory and motor areas, may be viewed as providing the brain with a second cortical subsystem with a higher level of discrimination than the cerebellum, capable of abstracting detail and of analytical sequential processing, and with the ability for more refined and elaborated control. Until recently the prevailing view in contemporary brain research is that cognitive functions are mediated almost exclusively by the cerebral cortex. The cerebrum is thought to be involved in the whole range of cognitive processes, including nonverbal communication, recognition and expression of emotion, visuospatial skills, imagination, mathematical processing, language skills (speaking, reading, writing), problem solving, planning, analytical and logical reasoning, and aspects of memory and recall.

There is evidence that the two cerebral hemispheres represent and process information in different ways and have different roles. The dominant (most often left) cerebral hemisphere is associated with information representation and processing, which is sequential or in series, digital, and abstract. It is characterized by analytical and logical processing that deals with detail. It plays a major role in the processing of verbal information, and in particular digital or abstract linguistic representation. Of the two cerebral hemispheres the dominant one is considered to be involved with consciousness, especially self-consciousness.

The minor (most often right) cerebral hemisphere is associated with information representation and processing, which is simultaneous or in parallel, analog, and holistic. It is characterised by Gestalt, analogical, and integrative processing, which deals with more spatial and global information and with novel or unfamiliar information. It plays a major role in the processing of naturomorphic or imagistic representations and in particular the processing of nonverbal and emotional information, spatial and pictorial information, and music and other non-language sounds.

One reason given for hemispheric specialization within the cerebral cortex is that it allows for the coexistence of two incompatible but complementary modes of information processing. To some extent this may be true; however, the two cerebral hemispheres have the same fundamental cytoarchitecture, have unimodal primary reception areas, and receive filtered input. In fact, much of the currently available information points to differences between the cerebral hemispheres that are merely relative or quantitative rather than qualitative. Furthermore, there is evidence from various sources that indicates that the cognitive processes attributed to one or the other of the cerebral hemispheres are not exclusive to that hemisphere. Most basically, the two cerebral hemispheres are both abstract in-series processors, but they appear to have different patterns of development. As a result of this differential development the dominant hemisphere appears to represent and process information at a much higher and relatively incompatible level of abstraction than that of the minor hemisphere.

Association areas within the minor hemisphere temporal lobe, particularly the inferotemporal region, are thought to be involved in emotional processes, experiential memory, and imagination. There is some evidence that the temporal lobe may not be the location of the experiential memory record, but that this information may be transmitted to the temporal lobe from subcerebral areas. Transmission from subcortical regions appears to involve the hippocampus and the brain stem monoamine systems. As noted earlier, the cerebrum projects to the cerebellar cortex and can contribute to cerebellar processing. However, it is also evident that the cerebellum projects to the cerebral cortex, including association areas, and can contribute to cerebral processing in the cognitive domain. Reciprocal interaction between the cerebral neocortex and the cerebellar cortex involves the hippocampus and the brain stem monoamine systems. A range of evidence supports the suggestion that Norepinephrine or its precursor Dopamine faciilitates excitatory output from the cerebellum to the cerebrum whereas 5-Hydroxytryptamine appear inhibit output from the cerebellar to the cerebrum. There is evidence of lateralization of neurotransmitter activity and lateralization of interaction between the cerebellum and cerebrum. It is therefore possible that some of the subcerebral input to association cortex processing is of cerebellar origin and that some of the cognitive processes attributed to the minor hemisphere cerebral hemispheres are of cerebellar origin.

In summary, the cerebrum is one of two cortical subsystems capable of cognitive processing of information from the environment and of controlling the behavior of the organism; in evolutionary terms, as a whole, it is the most recent to develop and therefore relates to later stages of cognitive development. It is particularly associated with conscious control and cognition. In information representation and processing terms the cerebrum may be described as a

sequential processing abstract subsystem of relatively high discrimination, and from this perspective it is complementary to the cerebellum.

CHARACTER DISORDER

The conception of character reflects mankind's understanding of human nature. Plato (427–347 B.C.) and Aristotle (284–322 B.C.) recognized individual differences; Hippocrates (460–377 B.C.) and Galen (130–200 A.D.) offered humoral theories of temperament, whereas Theophrastus (372–287 B.C.) described 30 character types, some of which resemble modern personality typologies. By the early nineteenth century psychopathology became linked to character. For example, Pinel (1801/1962) described insanity without delirium, Rush (1812) wrote about moral depravity, and Prichard (1835) advanced the concept of moral insanity.

According to Pierce's (1924) *The Philosophy of Character,* personality and character are equivalent; both reflect the sum of attributes of the person and the agglomeration of all knowledge, innate and acquired, teleological and nonteleological, which forces action, and thus, taken with the environment, determines the conduct of individuals. Similarly, Roback's *The Psychology of Character* (1927) defined character as the disposition to inhibit impulse and narrow self-seeking in light of some value principle.

From this traditional definition, the concept of character disorders evolved to include four rather diverse patterns of abnormal behavior: alcoholism, drug addiction, sexual deviancy, and psychopathy. Despite their diversity, several characteristics common to individuals so categorized were cited as justification for viewing them within a single conceptual framework. The behavior patterns typically constitute a violation of the codes and conventions of society. The problem behaviors most often result in immediate positive reinforcing consequences, although the delayed effects are usually negative. Finally, these individuals do not seem to experience guilt over repeated violation of societal conventions and are rarely motivated to change their behavior.

A slightly different meaning to the term *character* can be found within psychoanalytic theory. Early analysts began by investigating neurotic symptoms, phenomena that do not fit within a customary mode of behavior. Realizing the importance of these customary modes of "character" in the analysis of symptoms of therapeutic resistances, analysts began describing the nature of character and the role it played within the ego (see Fenichel, 1945). The publication of Reich's *Character Analysis* in 1933 was an impetus for the serious study of character types. It represented a shift in psychoanalytic theory away from unconscious material and toward the characteristic behavior that is used as a defense against analytic insight and unconscious material (Reich, 1972).

The most common example of character disorder is the condition classically designated as the psychopathic or sociopathic personality, the history of which has been comprehensively recounted elsewhere (Millon, Simonsen, & Birket-Smith, 1998). The psychopath seems to regard others not as persons, with feelings and rights comparable to his or her own, but as things to be used, exploited, and manipulated. H. Cleckley in *The Mask of Sanity* (1941) describes the psychopath as having superficial charm, untruthfulness, insincerity, poor judgment, failure to learn from experience, unresponsiveness in interpersonal relationships, and a failure to follow any life plan. Frequent involvement with criminal justice systems is common, along with participation in fraud and swindling activities. Modern assessment, such as Hare's (1991) checklist, preserves a set of core attributes: glib and superficial charm; grandiose sense of self-worth; need for stimulation or proneness to boredom; tendency toward pathological lying, conning, and manipulativeness; lack of remorse or guilt; shallow affect; callousness and lack of empathy; parasitic lifestyle; poor behavior controls; promiscuous sexual behavior; early behavior problems; lack of realistic, long-term goals; impulsivity; irresponsibility; failure to accept responsibility for own actions; many short-term marital relationships; juvenile delinquency; revocation of conditional release; and criminal versatility. Confusingly, the term *psychopath* is almost absent from widely accepted modern nomenclature, replaced by the more ubiquitous *Antisocial Personality Disorder,* which substituted more reliable behavioral criteria of lawlessness and deviance for richer, albeit less reliable, etiologic and theoretic formulations.

Alcoholism and drug abuse have traditionally been included under the heading of character disorders. Individuals with these symptoms generally show many dependency-autonomy conflicts and problems in the area of impulse control, conformity to social expectations, and personal value commitments that are common to a disorder of character. Similarly, sexual behaviors including exhibitionism, trans-

vestitism, voyeurism, sadomasochism, fetishism, rape, homosexuality, pedophilia, and incest have historically been included in this category. Modern classification systems have discarded the notion of character as defining in these disorders and have separated substance abuse and sexual paraphilias into discrete diagnostic categories. Likewise, in psychology's more recent history, *character disorder* is used as a generic term to refer to disorders of personality. Such disorders represent any deeply ingrained inflexible, maladaptive patterns of relating to, perceiving, and thinking about the environment and oneself. They may cause either significant impairment in adaptive functioning or subjective distress. Thus they are pervasive personality traits and are exhibited in a wide range of social and personal contexts. *The Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 1994) is one system of describing these conditions.

Finally, it is important to recognize that character disorders need not be exclusively defined by their clinical, symptomatic, or maladaptive components. Indeed, there are examples of constellations of traits that might be considered maladaptive in one setting but adaptive, perhaps even richly rewarding, in another setting. Widom (1977), for instance, has studied the personality profiles of noninstitutionalized psychopaths, ones who have never been caught. Works such as Lasch's (1978) *The Culture of Narcissism* and Smith's (1978) *The Psychopath in Society* have taken an even broader view by implicating certain character "disorders" as ascendant over aspects of modern culture and commerce.

In summary, character disorders, a slightly archaic term by standards of contemporary nomenclature, have their origin in conceptions of human nature and individual difference. As a class, character disorders subsumed a number of conditions for which a moral defect was believed responsible: alcoholism, drug addiction, sexual deviancy and psychopathy. Modern conceptions of character disorders are relegated to descriptions of Antisocial Personality Disorder, personality disorders in general, or Substance Abuse and Sexual Disorders.

CHI-SQUARE TEST

The chi-square (χ^2) test was developed by Karl Pearson in 1900, an event often regarded as one of the most important breakthroughs in the history of statistics. The test and the statistical distribution on which it is based have a wide variety of applications in psychological research. Its two principal uses are to test the independence of two variables and to assess how well a theoretical model or set of a priori probabilities fits a set of data. In both cases the chi-square test is typically thought of as a nonparametric procedure involving observed (O) and expected (E) frequencies. The expected frequencies may be determined either theoretically or empirically. The basic formula for calculating the chi-square statistic is

$$\chi^2 = \sum_1^k \left[\frac{(O - E)^2}{E} \right].$$

The χ^2 test is commonly applied to a wide variety of designs, including $k \times 1$ groups, $2 \times k$ groups, 2×2 contingency tables, and $R \times C$ contingency tables. It is most appropriately used with nominal-level (categorical) data but is frequently used with ordinal-level data as well. The χ^2 statistic is related to several measures of association, including the phi coefficient (ϕ), contingency coefficient (C), and Cramer's phi (ϕ' or ϕ_C). $\phi^2 = \chi^2/N$ is frequently used as a measure of practical significance or effect size for 2×2 tables.

Historically, there has been concern over the use of the chi-square test when any E was small (e.g., < 5–10) because the underlying χ^2 distribution is continuous whereas the distribution of observations is discrete. For 2×2 tables this led to the development of the widely used and recommended Yates' correction for continuity. However, most recent evidence seems to suggest that the use of Yates' correction is unnecessary even with very small E.

The χ^2 distribution is related to the normal distribution, such that the square of a standard normal deviate (z^2) is distributed as a χ^2 with one degree of freedom. The chi-square distribution also describes the sampling distribution of the variance, s^2, such that $\chi^2 = (N - 1)\, s^2/\sigma^2$ with $N - 1$ degrees of freedom. These relationships form the basis for many tests of statistical significance. For example, the analysis of variance F statistic may be thought of as the ratio of two χ^2 statistics. The χ^2 statistic is also used in many multivariate statistical tests and in calculating multinomial probabilities, especially for log-linear models. Multivariate statistics that use both generalized least squares and maximum likelihood procedures also rely on the χ^2 statistic. For example, in structural equation modeling, the χ^2 statistic forms the basis for many goodness-of-fit tests. In the 1930s, Fisher developed a procedure using the χ^2 test to combine the results of several independent tests of the same hypothesis, an early version of meta-analysis.

CHILD AND ADOLESCENT DEPRESSION

Clinical depression as seen in children and adolescents is characterized by depressed mood and/or loss of interest in activities as well as related symptoms such as difficulties with sleep, appetite changes, a sense of hopelessness, decreased energy, increased aches and pains, loss of self-esteem, difficulties with concentration, and thoughts of death and dying, sometimes with active suicidal plans. In some cases, young people do not complain of depressed mood or loss of interest in activities but instead have extreme irritability along with other symptoms. Most children, just like adults, have brief periods of depressed or irritable mood. Clinical depression (Major Depression) requires that several symptoms occur at the same time; persist for most of the day, nearly every day for a period of at least 2 weeks; and be associated with significant impairment in the child's ability to function. When clinical depression is causing impairment, parents and teachers may notice loss of interest in activities, increased arguments with others, decreased school attendance or performance, and loss of friends. Thus, many children may have brief periods of time (a few days) when they feel down in the dumps, typically after a disappointment. Parents and caretakers need to worry about clinical depression when many symptoms occur at the same time, persist over a period of a week or more, and are associated with a decline in school or family functioning and social participation.

Significant depression has been observed in young children, but depression appears to become more of a problem for children as they move into the adolescent years. At any point in time about 1 to 2% of children meet the criteria previously outlined for clinical depression; this rate increases to 4 to 8% of adolescents, and some research studies indicate that 25% of adolescents will have experienced a significant depression by the time they turn 18. Although rates of depression increase during adolescence for both boys and girls, gender differences begin to emerge between ages 13 and 15, with more girls than boys reporting depressive symptoms.

Periods of clinical depression can last for many months in some young people and can interfere significantly with a child's ability to keep up in school and remain active with friends. They can also be recurrent: As many as 40% of children and adolescents experience a second episode of depression within 2 years. Finally, depression is associated with substantial negative changes and risks both during and after the episode; these include difficulties in school and interpersonal relationships, increased risk of tobacco and substance abuse, suicide attempts, and completed suicide.

Although the cause of depression is not yet determined, it is thought that depression is most likely to occur when a number of risk factors come together. Biological vulnerability is one of these factors: Children whose parents have had significant depression are at a markedly increased risk for depression as well as other behavioral and emotional problems. Children may inherit a genetic risk for depression or temperamental qualities such as sensitivity to negative emotions, or they may learn depressive coping styles from their parents. Both adults and young people who are depressed share a depressive or negative way of thinking that leads them to view themselves, the world, and their future in a negative way. This is frequently described as seeing the cup as half empty, while others can look at the same situation and see the cup as half full. Many times depressed individuals come to see all failures as due to their own inherent faults but any success as pure chance or a fluke. This is called *negative attributional or explanatory style.* It is widely believed that depression affects a vulnerable person (based on biological, cognitive, or a combination of factors) when he or she is faced with stressful life events. For young people these events frequently include parental separation or divorce, geographic moves, loss of a friendship or romance, or exposure to abuse or neglect. Antidotes for depression include increased social support and social activity and learning skills needed to manage stress.

Efforts to both prevent the onset of depression in at-risk young people and treat depression in children and adolescents have been promising. A series of studies have de-

scribed the use of school-based, small group programs geared to increase problem-solving skills, decrease negative or depressive thinking patterns, and increase social supports in youths at risk for depression. Risk is typically determined based on the presence of a parent who is struggling with depression or a child's report of initial signs of depressive symptoms.

Two structured psychotherapeutic approaches have also shown promise in the treatment of youths who are clinically depressed. Cognitive-behavioral therapy (CBT) is a 12- to 16-week individual treatment approach that focuses on teaching how to identify and then challenge (change) negative thought patterns as well as how to increase participation in pleasant events and improve stress management and social support. CBT has been effective in reducing the negative thinking patterns of depressed youths. Interpersonal psychotherapy (IPT), another brief treatment (12–16 weeks), also has initial outcome data suggesting positive treatment effects. IPT stresses the importance of the youth's social relationships and sees depression as occurring when a young person is in the midst of a change in social role (i.e., the adolescent transition) or does not have the social skills or social support to maintain a sense of well-being. Initial studies of this approach indicate success in improving overall social function, which may in turn lead to a decrease in depressed mood. Finally, initial studies suggest that medication also plays an important role in the treatment of depression. Although carefully controlled studies are few, there is some evidence to suggest that the selective serontonin reuptake inhibitors, such as Prozac, are effective in reducing symptoms of depression, especially symptoms of sleep and appetite disturbance and the tendency to be caught up in recurrent worries and negative thoughts. At this time the recommended treatment approach for clinical depression in children and adolescents is psychotherapy with pharmacotherapy as an additional component when indicated, such as when sleep or appetite disturbance or recurrent worry is present or when the depressed mood is so severe that it interferes with psychotherapeutic efforts.

CHILD CUSTODY

Throughout history, different trends have occurred in custody determination. Prior to the 1920s, children were considered to be the property of the father, who almost always received custody. Starting in the 1920s, the Tender Years Doctrine was advanced, which assumed that young children were better in their mother's care. Consequently, a strong preference was given to the mother in regard to custody. This continued until 1970, when the focus shifted to the best interests of the child. At the present time, all states use this standard. However, specific criteria vary from state to state. Some common criteria include parenting capacity; mental and physical status of the parents; wishes of the parents and children regarding custody; home, school, and community adjustment of the children; and the willingness of each parent to facilitate the children's relationship with the other parent.

There are two major types of custody: legal and physical. Legal custody refers to decision-making power. Sole legal custody means that one parent holds all legal rights to decision making regarding the children, along with physical placement. Joint legal custody means the parents have equal legal rights and responsibilities for the children. Most states strongly support joint legal custody unless there is clear and convincing evidence that it would be detrimental. This position is advocated because it keeps both parents actively involved in major decision making regarding their children.

Physical custody refers to the physical placement of the children. Shared placement or joint physical custody means an equal or nearly equal distribution of time with the children. This is a workable plan when the parents live close to each other, conflict between the parents is minimal, children are able to deal with transition, and the children's age and developmental needs support such a plan. However, in the majority of cases, the children reside predominately with one parent, with designated parenting time (e.g., visitation) with the other parent. Parenting time plans vary widely and need to be developed to meet the individual needs of the parties. Some factors often considered are work schedule(s) and availability of the parents, geographic distance between the parents, age and developmental needs of the children, special needs of the parents and children, degree of cooperation between the parents, and desires of the parents and children. A couple of common plans are (1) the noncustodial parent having the children every Wednesday evening and every other weekend, and (2) the noncustodial parent having the children every weekend or three of the four weekends per month and one evening before and after the nonvisitation weekend. During the summer, the parenting plan may continue, or the time may be equally divided between the parents. Holidays and vacation breaks are usually divided or alternated between the parents.

In the overwhelming majority of child custody cases, the parents are able to come to an agreement regarding legal and physical custody. However, in about 10% of the cases, custody becomes contentious. In these cases, the court sometimes orders a child custody evaluation. This type of forensic evaluation is performed by a clinic affiliated with the court or by a private practice mental health professional with specialized training and experience in the child cus-

tody field. Evaluations performed by a court clinic are usually brief, taking 4 to 8 hours to complete, with a two- to five-page report to the court. Cost is usually minimal or determined by a sliding scale. Evaluations performed by private mental health professionals are usually very comprehensive and costly. Private practice doctoral-level psychologists usually take 25–30 hours to complete the evaluation. Reports to the court are typically about 20 pages but may vary depending on the complexity of the case.

The court should appoint the child custody evaluator, thereby allowing the evaluator to function in an independent, objective, and impartial role. The evaluator should not have a prior relationship with the family (i.e., as therapist). The focus of the evaluation is the best interests of the children. The evaluator needs to address the specific best-interest criteria established by state law. All parties need to be involved in the evaluation process, because the evaluator needs to critically evaluate both sides of the dispute. Also, an evaluator cannot provide an opinion about a person not seen. In contrast to therapy, court-ordered evaluations have limited confidentiality, meaning that all information gathered during the evaluation may be reported to the court. Guidelines for performing child custody evaluations are provided by professional organizations. For example, the American Psychological Association has published the *Guidelines for Child Custody Evaluations in Divorce Proceedings,* which outlines parameters for professional practice in this area.

Multiple methods of data collection are used in child custody evaluations. The following components are critical in the evaluation process: (1) interviews with each parent to gather a comprehensive psychosocial history and explore the marital history and dispute; (2) interviews with each child; (3) parent-child observations; (4) psychological testing of the parents, and children if needed; (5) collateral contacts with important individuals, such as new partners, therapists, teachers, or babysitters; and (6) review of pertinent documents and court records. In terms of psychological testing, parents are frequently given personality measures to assess personality traits and characteristics, along with signs of mental illness. Also, parenting inventories are increasingly being used to assess parenting attitudes and beliefs.

Many times in these contentious cases an allegation of sexual abuse, domestic violence, substance abuse, or parent alienation is made. Many different motives are involved in these allegations. Sometimes it is a genuine concern for the children's welfare; however, at other times the allegation is used in a vengeful, vindictive way to gain leverage in the dispute. These types of allegations require much investigation and a high level of expertise on the evaluator's part.

The average amount of time to complete a child custody evaluation is usually 2 months. A report is provided to the court regarding the findings and recommendations. Judges consider the report, along with other data, in making the ultimate decisions regarding custody and parenting time.

CHILD GUIDANCE CLINICS

The National Committee for Mental Hygiene marshaled the child guidance clinic movement, which spanned the decades of the 1920s to 1940s. Child guidance clinics were established for the psychiatric study, treatment, and prevention of juvenile delinquency, other social ills, and conduct and personality disorders in 3- to 17-year-old non–mentally retarded children. The child guidance clinic approach to children's mental health represented a shift from traditional treatment models of the era, which were largely individual psychoanalytically oriented play therapy sessions conducted by a psychiatrist or psychologist, toward more innovative modes of intervention. Child guidance clinics' comprehensive, community-based approach to children's mental health service was carried out by multidisciplinary teams of psychologists, psychiatrists, psychiatric social workers, speech therapists, and psychiatric occupational therapists. In the 1940s the mental health focus shifted from the child guidance clinic movement to World War II–related mental health issues.

The next large impact on children's mental health services was the Community Mental Health Centers (CMHCs) Act of 1963. Like child guidance clinics, CMHCs sought to address both the treatment and prevention of mental illness within communities. However, unlike child guidance clinics, CMHCs were not solely child focused, rather, they addressed mental health issues across development, from prenatal health to coordination of services for the elderly at individual, family, and community levels. CMHCs were responsible for a comprehensive menu of services including outpatient treatment, primary and secondary prevention efforts, 24-hour crisis response, and community mental health education. CMHCs fulfilled their community education responsibility through consultation with schools in the area of early child risk evaluation.

Partly in response to changes in insurance reimbursement systems such as health maintenance organizations, mental health services for children have continued to evolve. Currently they include varied theoretical orientations and treatment approaches. Current work with chil-

dren emphasizes child-centered, family-focused, community-based efforts in the planning and implementation of treatment. Mental health services strive to be both culturally competent and responsive to the cultural, racial, and ethnic differences within varied service populations. Services available to children within the mental health system include inpatient and outpatient psychiatric and psychological treatment facilities, partial programs, mobile therapy, crisis teams, foster care, juvenile justice, education, social welfare, primary health care, emergency shelter, and home-based interventions. In addition, wraparound services that meet a child's mental and physical health needs across his or her varied environments have been added to the children's mental health service menu. Case managers, whose job it is to coordinate children's mental health services within this complex system, have emerged to ensure that services are not fragmented and work in an interactive therapeutic manner to meet children's mental health needs. Undoubtedly, the mental health service system will continue to evolve in an effort to meet children's ever-changing physical, emotional, social, and educational needs.

CHILD NEGLECT

Child abuse and child neglect are the two forms of child maltreatment. Abuse requires deliberate action; neglect is a failure to act in ways necessary to nurture or protect a child. The forms are similar in that they can be emotional, educational, medical, sexual, or physical, and both are extremely harmful. Abuse might seem worse and more common. However, neglect is actually more common, more destructive, and more deadly.

More than half a million children in the United States are severely neglected each year (these are reported and substantiated cases; millions more are not reported). Worldwide, 1 billion children are neglected annually, a number that becomes believable if you remember that, of the world's 2 to 3 billion children, many suffer chronic malnutrition, exposure to violence, or lack of medicine.

Within the United States, for every child who is abusively murdered, at least four die of neglect: They starve, die of illness, or perish in preventable accidents. Fortunately, if neglect is recognized early on as pervasive and destructive, it is preventable before permanent damage to a child occurs.

Emotional Neglect

From a psychological perspective, *emotional neglect* is the most serious form of neglect, in that the consequences of ongoing emotional neglect are lifelong: An emotionally deprived child becomes an adult who rarely experiences the joy, love, and intimacy that make life worth living. Emotional neglect begins in infancy. If babies cannot establish normal attachments, perhaps because their caregivers are depressed, drug-addicted, emotionally immature, or overwhelmed by their own survival needs, then infants and toddlers become detached from social relationships. The damage occurs within the brain, during formation of synapses and dendrites, and thus is difficult to reverse later on.

Typically, neglectful caregivers continue their emotional distancing throughout early childhood, never teaching the child about love, fear, anger, or sadness. By the time they reach school age, emotionally neglected children cannot regulate their emotions: They are too fearful, too depressed, or too aggressive. They become bullies, or victims, or friendless. They have never learned to distinguish hostile anger from innocent mistakes, genuine warmth from superficial friendliness. As adolescents and adults they befriend people who exploit them or provoke people who will hurt them, often becoming antisocial, bitter, and lonely.

Educational, Medical, and Sexual Neglect

Another type of neglect is *educational neglect*. All children are eager to learn, from the moment they are born. Early on, they need to learn language, which means that someone must talk to them and listen to them many hours every day. A 1-year-old who is not speaking, or a 2-year-old who is not using simple sentences, may be the victim of educational neglect. Preschoolers learn through active play and safe exploration; they are neglected if they sit alone or watch television for many hours each day instead of playing. Parents who do not send their school-age children to school, and schools that do not teach every child all the basic skills, are educationally neglectful.

Medical neglect is failure to meet a child's medical needs for protection against disease and for treatment. Basic immunizations against polio, tetanus, whooping cough, mumps, measles, and even chicken pox, as well as treatment for high fevers, painful earaches, broken bones, deep cuts, concussions, diarrhea, and so on are part of good care for every child. When they are not provided, parents, doctors, and communities are neglectful. One sign of child abuse is missed immunizations and untreated traumas, because medical neglect is often the first warning sign for later abuse.

Sexual neglect occurs when a child is not protected from sexual exploitation. Children not only need privacy, but they also need to develop respect for their own bodies. Before puberty, children need to know not only how to avoid sexual diseases and unwanted pregnancy, but also how to love themselves and another person. Loving mothers and fathers teach them this by example.

Physical Neglect

Failure to meet basic food, rest, and shelter needs is *physical neglect,* the most commonly reported form of neglect. If an infant grows very slowly, that can be *failure to thrive.* Slightly older children (aged 2–10) may suffer *deprivation dwarfism:* They are unusually short because too much stress (especially when it occurs at night, when most growth occurs) slows down their growth.

Children also need ample sleep, not only for growth but also for brain maturation and intellectual alertness. Cultures vary in sleeping arrangements: Some families believe children need their own rooms, and other families believe children should never sleep alone. From a psychological perspective, neither practice is necessarily neglect. However, failure to shield a child from witnessing domestic strife and violence may cause posttraumatic stress, with one symptom being vivid nightmares. Routinely waking the child from a sound sleep is also neglectful. Schools that begin early in the morning may ignore normal body rhythms (many teenagers are at least half asleep until noon).

Exposure to hazards—motor vehicles, swimming pools (drowning is the leading cause of accidental death for 1- to 4-year-olds in 10 states, including California, Florida, Arizona, and Texas), fires, poisons and so on—is neglect as well. Most accidents to children are preventable. For example, laws requiring car seats and safety belts have reduced the child motor vehicle death rate by half. Fatal fires could be much less common—they are seven times more likely if a caregiver is drunk, five times more likely when dwellings are run-down and crowded, and three times more likely if there is no working smoke detector. This is just one example that reveals that social neglect underlies many child deaths.

Note that we have not stressed psychological disorders as a cause of child neglect. Some parents have severe emotional disturbances; some children are hyperactive, or rebellious, or learning disabled. Such inadequacies are real, and they increase the risk of child neglect. However, psychologists consider neglect more of a social and community problem than an individual one; everyone needs to recognize it and take whatever action he or she can. When caregivers are inadequate, the entire community can prevent the harm that occurs from child neglect.

CHILD PSYCHOLOGY

Child psychology deals with the personality and behavior of children, typically from conception to puberty. In the past *child psychology* has referred to both normal and abnormal behavior, to both theory and research, and also to the psychotherapy or counseling of disturbed children. Current usage, however, limits the term to a branch of the *science* of developmental psychology, specifying "child clinical" when referring to the professional practice of child psychology.

Childhood can be divided into substages: prenatal, infancy, toddlerhood, preschool, middle childhood, and later childhood. Some researchers, however, argue that development is best understood in the context of the total span of life and propose a "life span developmental psychology." Additionally, current research has focused on the contexts that influence development, including the family, school, and peers (see Bronfenbrenner, 1989, 1993).

History

Four sorts of history can be considered. Ontogenetic history, the history of the organism from conception to death, is the basic material of human development. Phylogenetic history refers to the evolutionary development of the species. According to one theory—proposed by G. Stanley Hall in his treatise *Adolescence* (1904), but now largely discounted—the ontogenetic history of individuals represented a "recapitulation" or repeating of the species's phylogenetic history.

A third sort of history refers to changes over time in the concept of childhood, corresponding to the sociocultural history of the family. Philippe Müller (1969) identified four periods in the cultural history of the family that corresponded to changing conceptions of the child.

A fourth kind of history in child psychology is the history of the field itself. Early Greek writers were concerned with stages of development, the socialization process, and the proper education of children. The origins of child psychology as a science, however, can be traced to the careful observations recorded in early "baby biographies," such as those written by Tiedemann (1787), Darwin (1877), and Preyer (1888/1882). Despite their shortcomings as scientific data, these biographies paved the way for more careful observation, for attention to psychological processes, and finally for experiments dealing with child behavior.

More recent influences on child psychology have been the testing movement and the development of child guidance clinics and major university centers for research on child behavior. Current literature emphasizes developmentally appropriate guidance, that is, optimal ways to work with and parent children.

Theories

Early theories of child psychology were largely implicit, children being thought of as miniature adults. Not until the late nineteenth century and the emergence of a formal discipline of psychology did theories about child behavior become prominent. An early psychologist, G. Stanley Hall, proposed a biogenetic theory emphasizing biological growth and genetic predispositions.

Freud, the father of psychoanalysis, emphasized environmental and especially social factors in the development of child behavior and personality. One of the first to stress the influence of early experience on later behavior, Freud assigned a major role to the unconscious. He postulated a series of psychosexual stages defined by the characteristic way in which libido, or mental sexual energy, gets expressed (see "Psychosexual Stages").

Jean Piaget developed a major theory of cognitive development. For Piaget, the stages of development concern the increasingly complex way in which the individual can incorporate and process information and assimilate it into his or her own previously developed mental structures.

Learning theorists have tended to view children's behavior as based on environmental rather than organismic factors and, like Freud, see the organism as passive rather than active in its own development. The emergence of social learning theory was in some respects a combination of psychoanalytic and learning theory concepts.

Research Methods

Since the days of the baby biographies, child psychology has progressed in methodology as well as theory. Using a *longitudinal* approach, investigators follow the same subjects over the years of interest and observe age changes. With the *cross-sectional* approach, the researcher tests subjects of different ages. A combination of the two procedures has been suggested (Schaie, 1970) as a more powerful approach.

Research methods have included questionnaires; ratings and rankings by teachers, peers, parents, and oneself; interviews; observation; projective tests; personality and intelligence tests; and direct experimentation. A good source for understanding the basic information on research methods in child psychology is *Research Methods in Human Development* (Brown, Cozby, Kee, & Worden, 1999).

Issues In Developmental Psychology

The contrasting views of the child as an active agent or a recipient remain a salient issue in child psychology. The relative influence of environmental factors, contrasted with genetic predispositions, is also an important dimension to child psychologists. Finally, child psychologists differ in the importance they place on stages in development: While some theorists perceive development as proceeding by discrete stages, other assume a more continuous unfolding of personality and behavior.

CHILDHOOD DEPRESSION

Diagnosis, Prevalence, and Prognosis

A depressive disorder is defined by a disturbance in mood and a cluster of emotional, cognitive, vegetative, and behavioral symptoms that result in functional impairment. Typically, depressive disorders are episodic. There are two diagnoses of unipolar depressive disorders: Major Depressive Disorder and Dysthymic Disorder. Major depression is a more severe disorder in terms of the number and quality of symptoms and the extent of functional impairment. Dysthymic Disorder is less severe but longer lasting. A child may experience both of these disorders at once.

Prevalence rates are increasing with each successive generation. Prevalence increases with age and differs across subgroups and diagnostic categories. Depressive dis-

orders are rare among preschool children. Among children, rates of 2% are reported for major depression and 2–3% for Dysthymic Disorder. Twenty percent of adolescents report symptoms of major depression, with the rate increasing dramatically at puberty. Females, African American children, and children with a medical condition or learning disability are at greater risk for developing depression.

Children's depressive disorders tend to be longer and more severe than those of adults. Although most children will recover, depression can leave them socially, cognitively, and educationally impaired. Several variables including severity, family dysfunction, and gender predict the duration of a depressive episode. The average duration of a major depressive episode is reported to be 32 to 36 weeks, with longer durations in females. The rate of recovery is slow, with the greatest improvement starting between the 24th and 36th week. Within 6 months of onset, the depressive episode has remitted for 40% of the children. At one year, 80% of the children are no longer experiencing a depressive episode. The average duration of dysthymia is 3 years. A chronic course is reported for a significant percentage of depressed children. Depressive disorders are recurrent, with about 75% experiencing another episode within 5 years. Most depressed youths simultaneously experience additional psychological disorders. Occurrence of a psychotic depression or comorbid Attention-Deficit/Hyperactivity Disorder (ADHD) may be risk factors for later development of bipolar disorder.

Etiology

There are a number of possible biological and psychosocial causes of depression. The most widely accepted theories of depressive disorders are stress diathesis models, in which stress interacts with a genetic or psychosocial vulnerability to produce a depressive episode.

Most biological theories of depression assume that the diathesis is a dysfunction of one or more neurochemical systems in the brain. The biogenic amine theory suggests that depression is caused by depletion of monoamines (norepinephrine, serotonin, and dopamine) at critical synapses in the brain (Schildkraut, 1965). There is an increasing appreciation of the synergistic action of multiple neurotransmitter systems. Hormonal, neuroendocrine, and hypothalamic-thyroid systems may also be involved in depression.

A number of psychosocial models of childhood depression are empirically supported. The cognitive model suggests that a depressive disorder originates with a disturbance in the child's thinking. Beck's (1967) cognitive theory of depression describes a disturbance in the memory structures that guide an individual's attention, construction of experiences, and other thought processes. According to the learned hopelessness model of depression (Abramson, Metalsky, & Alloy, 1989), the individual questions the occurrence of a negative or stressful event; the answer to the question is referred to as an *attribution* and affects the youngster's emotional adjustment. Depressed individuals have an attributional style that leads to feeling helpless. Additional theories focus on deficits in areas such as (1) interpersonal relationships, (2) emotion regulation, (3) social skills and problem solving, and (4) personal competence. No single theory seems to account for all cases of depression.

Assessment

Clinicians use a multitrait, multi-informant, and multimethod approach to assess childhood depression. These assessments usually consist of paper-and-pencil measures and a diagnostic interview completed by the child and parents. The questionnaires and interview are designed to assess the presence and severity of depressive symptoms. The experience of depression is subjective, so the child is the primary informant, with parents providing information about the onset and duration.

Treatment

Both medication and psychological treatments have been successfully employed with children. Currently, there are four main classes of antidepressants that may be prescribed to youths: tricyclics, monoamine oxidase inhibitors, selective serotonin reuptake inhibitors (SSRIs), and second-generation antidepressants. The antidepressants act on the monoamine neurotransmitter system, more specifically the neurotransmitters acetylcholine, norepinephrine, serotonin, and to a lesser extent dopamine. Antidepressant medications influence the metabolization and/or reuptake of the neurotransmitters producing increased levels of functionally available neurotransmitters. Most antidepressants have a broad spectrum effect, influencing the metabolization and/or reuptake of acetylcholine, norepinephrine, serotonin, and dopamine. A few are more focused, targeting specific brain monoamine systems. Current research indicates that SSRI treatments are beneficial for many depressed youngsters due to their efficacy, safety profile, and fewer reported side effects (Ambrosini, Emslie, Greenhill, Kutcher, & Weller, 1995). The presence and types of comorbid conditions are important determinants in choosing an appropriate medication. The recommended length of a medication trial is 6 to 10 weeks. If the medication does not show results during this period, then another antidepressant or an augmentation strategy with a different class of medications may be initiated. In a successful medication regimen, the recommended duration of treatment ranges from 2 months to 2 years.

Research has also supported the efficacy of cognitive-behavioral treatments for depressed youths. Cognitive-behavioral interventions are time-limited, structured interventions designed to change the depressed youngster's maladaptive thinking, behavior, and coping patterns. The child and therapist form a collaborative team in which the child is taught emotion regulation skills, coping skills, so-

cial skills, problem solving, and strategies for identifying and altering negative thoughts. The overall treatment goal is changing the individual's basic rules for interpreting daily interactions. Caregivers or the entire family may be included in the treatment program.

CHILDREN'S BEHAVIORAL STAGES

Studies of human development indicate basic principles underlying all developmental processes that lead to a series of stages that all individuals can be expected to go through. These principles are related to heredity as it interacts with environment and time during critical or sensitive periods and maturation. Indications of a stage development approach can be found in the work of Arnold Gesell, Jean Piaget, Lawrence Kolberg, Sigmund Freud, Erik Erickson, and others. These theorists generally think of development as a genetically determined sequence interacting in a continuous and, so to speak, creative fashion with the environment.

From birth onward there are new stages in motor, cognitive (thinking), and personality development to be considered. The organism is now in a position to be observed, and much more rigorous research is possible. At birth every infant has a repertoire of reflex behaviors to carry on everyday activities. In addition, sensory awareness begins to develop at a faster pace. Touch appears to be the only completely active sense at birth, but vision and hearing are even more advanced in their development than specialists considered possible only a short time ago.

Development in the womb and after birth follows three basic sequences. The first goes from the head downward in the body and is known in the literature as *cephalocaudal development.* The second is from the center of the body outward, known in the literature as *proximodistal development.* The third is the change from the massive generalized responses seen initially to the more specific later responses, indicated in the literature as a movement from gross to refined movements.

Arnold Gesell, who was interested in the genetically determined or maturational aspects of development, founded the Yale Clinic of Child Development at Yale University. He was concerned with the unfolding of inner tendencies rather than the changes resulting from learning or experience. Gesell concluded that behavior occurred in an unvarying sequence and that maturational changes made new kinds of behavior possible. He believed that knowledge about the maturational readiness of a child was essential for developing the best educational and training programs.

Behavioral norms for many aspects of child development were obtained and published in *Developmental Diagnoses: Normal and Abnormal Child Development,* by A. Gesell and C. Amatruda. The behaviors described in this publication are set up on a normative basis in such a way that 50% of the children examined at a particular age level will demonstrate the behavior under consideration, 25% will not have achieved that level of behavior as yet, and 25% will be beyond it. The norms are developed and presented in this form to help parents make decisions in regard to their own children. The norms enable parents to know what normal behavior can be expected and to be aware of developmental problems that may exist. Although Gesell stressed these norms in his work, he was also sensitive to differences among children and did not want the norms to obscure individuality of development.

Some psychologists think that Gesell overgeneralized in reporting his developmental growth stages. However, some conclude that his work on sequential levels of development, and his indication that growing stages are major periods of reorganization followed by periods of integration of the changes that have taken place, added a great deal to our understanding of how a child changes while maturing.

Jean Piaget considered development to be a continuous and creative interaction between the organism and the environment. He noted that both body and sensory activities contribute to a child's development of intelligence, and he stressed the need for adequate stimulation in the early years. Piaget concluded that the child's developmental stages dealt with specific cognitive behaviors that gradually and predictably changed in some specific order.

Piaget found four major stages, each of which contained consistent ways of dealing with the world different from the other three. The stages are sequential, and an individual must pass through all four of them. At the same time the stages are not rigidly fixed in a time sequence: They can overlap to some extent, and the ages at which a stage is to appear are only approximate.

The four stages that Piaget identified were (1) the sensorimotor stage, from birth to approximately 2 years of age; (2) the preoperational stage, from approximately 2 to 7 years of age; (3) the concrete operations stage, from approximately 7 to 11 years of age; and (4) the formal operations stage, from approximately 11 to 15 years of age.

In the *sensorimotor stage* the infant is learning to use the body and is gaining immediate experiences through the senses. All activity is practical and based on immediate experiences.

The *preoperational stage* finds the child beginning to use words and solve more complex problems. Children can move from one- or two-word sentences, at age 2 years, to eight- or ten-word sentences at around 5 years of age.

The *concrete operations stage* brings a literal, concrete way of thinking and a tendency to give up the magical thinking of the previous stage. Reasoning during this period is based on concrete examples, and each experience is considered as unique and not related to another experience.

The *formal operations stage* is when rational patterns of thinking are able to develop. Symbolic meanings are understood, and abstract strategies are possible. Hidden meanings can be understood, and generalizations from stories and games become a possibility.

Piaget sees these changes as part of an individual's movement toward a state of equilibrium. A well-balanced set of ideas organized into a workable mental system can be used to solve new problems.

Children assimilate particular kinds of experience at each stage of development, as they perform activities they already know how to do by using their new level of awareness. Accommodation occurs when children internalize these experiences and make them a part of their new capability.

Freud is considered a major developmental theorist with a stage-dependent approach. His theory of psychosexual development stresses the fact that certain early experiences during sensitive periods have lasting effects on the individual. He hypothesized five basic stages of development, with each stage characterized by a new socialization problem facing the individual. Stage 1 is the *oral stage,* which goes from birth to 1½ years of age; stage 2 is the *anal stage,* which lasts from 1½ to 3 years of age: stage 3 is the *phallic stage,* which lasts from 3 to 7 years of age, during which the child becomes aware of genital differences and the pleasures related to the genital area, such as masturbation. The Oedipus complex and the castration complex appear at this time. Stage 4, the *latency stage,* lasts from 7 to 12 years of age, a period when primary love interests are diverted to individuals outside the home. The basic personality has been formed by this time and becomes more or less stabilized during this stage. This period is often considered a calm before the storm of pubertal change. Stage 5 is the *genital stage,* which lasts from 12 years of age into the adult period of life. This is a period when the instinctual sexual drives increase, parental attachments are dissolved, and adolescent conflicts develop.

Freud believed that if the first three stages are completed without psychic trauma, the individual will tend to be psychologically healthy. If, however, some of the basic needs are frustrated, personality development will be arrested or fixation will occur and the personality will be affected at all later stages.

Similar to Piaget and Freud, the neo-Freudian Erik Erikson believed in a stage-dependent approach. He disagreed with Freud's psychosexual concepts because he believed that they were too narrowly conceived and that personality is not totally defined in early childhood but continues to develop throughout life. He evolved an eight-stage psychosocial development sequence, with his early childhood stages almost a duplicate of Freud's.

Lawrence Kolberg sees moral development as a universal cognitive process that proceeds from one stage to the next in a definite and fixed fashion at a pace determined by the individual's opportunities and experiences.

CHILDREN'S FEARS

Because fear is an emotional response to a perceived threat, it provides a protective survival mechanism by alerting the individual to danger. Mild or moderate fear reactions are viewed as normal and adaptive, promoting caution when real danger is present. However, fears become maladaptive when they are intense and persistent, alerting the child in the absence of potential danger, and interfering with normal physical, social, and intellectual functioning.

Psychologists generally distinguish between two types of fear: (1) *phobia,* an intense and to some extent irrational fear directly associated with specific objects, events, or situations; and (2) *anxiety,* a vague feeling of apprehension, uneasiness, or impending doom that has a relatively uncertain or unspecific source. Although the particular fears a child will develop—and their severity—cannot be predicted accurately, some generalizations about gender and age factors in the development of fears can be made.

Gender and Age Differences

Researchers have found consistently that girls report a greater number of fears than do boys. However, one cannot tell from these studies whether this gender difference is due to a higher inborn fear reactivity in females or whether other factors, such as sex-role influences, are responsible.

Several studies have found age-related changes in the *type* of fear children report. An overview of this developmental trend reveals that, as children grow older, their fears tend to become (1) more abstract and (2) more anticipatory, rather than being tied to immediate occurrences. For instance, compared to young children, older children tend to be less afraid of animals but more fearful of school and social relations.

Infancy and the Toddler Stage

Normal babies are born with startle or fright reactions to pain, to loss of physical support, and to sudden loud noises and flashes of light. Two common fears of infancy and the toddler stage are fear of strangers and fear of separations.

Preschool and Early School Years

Among the more common fears that develop in early childhood are (listed alphabetically) animals and insects; dark, especially at bedtime; death, often related to separation distress; doctors and dentists; heights; monsters and imaginary creatures such as ghosts and witches; school, often related to separation distress; storms and other natural events; and deep water.

Middle Childhood to Adolescence

In later childhood, a frequent theme underlying children's fears is the threat of physical injury from criminals and from machinery such as cars and airplanes. However, the most distinctive trend during this age period is toward increasing worry about school, individual competence, and social relationships—worries that continue into adolescence.

Sources of Fear

The process by which fears are acquired seems to involve three factors:

1. *Inborn sources.* Each baby enters the world with certain dispositions or basic personality traits, called *temperaments.* The temperamental styles of individuals seem to be enduring and appear to make some children vulnerable to the development of fear. These children may be more affected by and less able to cope with stressful experiences.
2. *Experiences.* Direct encounters with negative events can lead to fear by way of classical conditioning: The ability of a previously unfeared stimulus to elicit fear is increased when it becomes associated with an event that already elicits a fear reaction.
3. *Thinking and imagination.* Fears can also arise out of children's imagination, particularly when incorrect ideas and faulty reasoning are involved.

Treatment

Children can be helped to cope with fears before they become serious problems. When therapy is needed, two of the most effective treatments for fear reduction are counterconditioning and modeling. In *counterconditioning* a calm, relaxation, or coping response is substituted for the fear response by way of classical conditioning procedures, in which the feared object is gradually paired with pleasant or neutral events. Therapeutic *modeling* is a procedure in which the child observes other people in progressively more active or direct encounters with the feared object.

CHRONIC FATIGUE SYNDROME: CLINICAL DISORDER

Chronic fatigue syndrome (CFS) is a disabling condition characterized by severe, relentless fatigue that does not improve with sleep or rest and often worsens with physical or mental activity. Individuals with CFS are unable to perform activities that they were once able to perform without difficulty, such as working a full-time job or maintaining the tasks of daily living, such as household chores or grocery shopping. Specifically, CFS involves 6 or more months of unexplained fatigue that interferes with previous levels of occupational, educational, or social performance. According to the most recent U.S. diagnostic criteria issued by an international panel of experts headed by Dr. Keji Fukuda in 1994, at least four of eight additional physical and cognitive symptoms persist with the fatigue for at least 6 months. These include sore throat, swollen or tender lymph nodes, difficulties with short-term memory and concentration, muscle pain, multijoint pain, increased fatigue and symptoms following exertion, headaches, and unrefreshing sleep. In addition to these eight primary symptoms, a number of other symptoms have been reported by 20–50% of CFS patients, and may include nausea, abdominal pain, diarrhea, alcohol intolerance, dizziness, lightheadedness, weakness, dry eyes or mouth, bloating, chest pain, irregular heartbeat, chronic cough, and psychological distress involving feelings of depression and anxiety.

CFS can exhibit drastic fluctuations in symptom severity and level of impairment between and within individuals. A person who had been unable to leave his or her home may occasionally feel well enough to leave the house, take short walks, and converse with others. On the other hand, a usually high-functioning individual may experience a "crash" and be unable to perform his or her usual responsibilities for weeks or even months. A significant portion of these patients report some level of improvement over time

but only a minority (less than 10%) appear to achieve substantial recovery. Although prevalence estimates vary between studies, the average estimate is 200–422 individuals per 100,000 persons. The syndrome affects a wide range of individuals from varying racial, ethnic, and socioeconomic backgrounds. It affects both sexes, but it tends to be more common in women than men. Although less prevalent, CFS has been found to exist in adolescents and school-aged children. The level of co-occurrence of CFS with conditions such as fibromyalgia and multiple chemical sensitivities appears to be high. Because these conditions show moderate symptomatic overlap with each other, some have suggested that they are variations of the same underlying disorder. However, factor analytic studies suggest that, despite commonalities in symptomatology, these illnesses can be considered distinct entities.

The cause of CFS has not yet been determined, and as yet there is no specific diagnostic procedure or laboratory test that can definitively diagnose CFS. Debate regarding the medical legitimacy of CFS has entered into a number of important domains involving assessment and treatment. Some emphasize the role of psychological agents in the etiology and course of CFS and consider individuals with CFS as having a form of somatic depression or a variant of hypochondriasis. Others underscore the role of social-environmental factors in CFS, employing models of a dialectical relationship between body and society, in which somatic symptoms are interpreted as the sequelae of painful or otherwise exploitative social interactions. Still others emphasize the biomedical correlates of CFS, highlighting distinctions between CFS and psychiatric disorders such as depression. Although CFS is generally associated with higher than expected rates of psychiatric comorbidity as compared to the general population, research suggests that rates of psychiatric disorder observed in individuals with these conditions are no higher than those observed in other medically ill populations. Moreover, the failure to identify symptomatic overlap between these illnesses and psychiatric disorders may result in misleading overestimations of psychiatric comorbidity in psychodiagnostic studies. It is likely that some of the psychiatric disorders that are observed in some individuals with these illnesses are triggered by the personal devastation resulting from symptoms, functional impairments, and resource losses. Despite this controversy, a majority of researchers and practitioners acknowledge some distinction between CFS and psychiatric illness or support a biopsychosocial model for understanding the etiology and course of CFS in which biological, psychological, and social variables interact in the onset and maintenance of the syndrome.

Pathophysiological findings in microbiology, immunology, endocrinology, and neuroscience suggest that CFS cannot be explained solely by psychiatric factors, and laboratory studies have detected differences between individuals with CFS and those with primary depression on a number of indices. Almost every investigation of psychiatric comorbidity conducted to date has found an absence of diagnosable psychiatric illness in at least one quarter to one third of individuals with CFS (Wessely, 1998). Currently, research supports the idea that multiple precipitants may converge to form a single causal pathway to CFS. Some of these causal agents include viral and bacterial infectious agents, immune dysfunction, abnormalities of blood pressure and heart rate regulation, nutritional deficits, and other acute physical or emotional stressors: Alterations in the hypothalamic-pituitary-adrenal (HPA) axis that perhaps lead to abnormalities in immune functioning have also been postulated.

No curative medical interventions are available for any of these conditions. In part, this problem explains why many individuals with these conditions report negative experiences with treatment providers and with physicians in particular. Many physicians rely solely on palliative pharmacological agents, refer individuals with CFS for psychotherapy, or recommend no treatment whatsoever. Pharmacological management has been found to be helpful for certain individuals. Activity pacing, energy conservation training, and cognitive-behavioral therapy with graded activity have been used effectively to improve coping and in some cases improve functioning. Multidisciplinary approaches that include medical supervision, nutritional counseling, physical therapy, social support, psychotherapy, and medication management may produce the most favorable outcomes. In addition to these approaches, many patients dissatisfied with Western medicine have utilized alternative medical treatments, such as acupuncture and massage therapy for pain reduction.

CHRONIC FATIGUE SYNDROME: RESEARCH

Clinical Presentation

Although diseases similar to chronic fatigue syndrome (CFS) have been recognized for centuries under various rubrics, strict diagnostic criteria for conditions dominated by medically unexplained chronic fatigue were first proposed in 1988. Current diagnostic criteria were crafted in 1994 by an International Chronic Fatigue Syndrome Study Group as an attempt to standardize patient populations included in research studies. The International CFS Re-

search Case Definition requires the presence of at least 6 months of persistent, unexplained fatigue that interferes with multiple domains of daily life, is not relieved by rest, and is accompanied by at least four of the following symptoms: cognitive impairment, sore throat, tender neck or lymph nodes, muscle pain, joint pain, headaches, unrefreshing sleep, and more than 24 hours of post-exertional malaise. Importantly, the research case definition precludes classification as CFS if a patient has an identifiable medical cause to be fatigued. Similarly, subjects with certain psychiatric conditions cannot be classified as CFS in research studies. Exclusionary psychiatric conditions include Schizophrenia, bipolar disorder, or melancholic major depression. It is important to realize that the CFS case definition was devised for research purposes, and the concept of exclusionary conditions is critical to avoid confounding CFS with other medical disorders. In clinical settings the list of exclusionary conditions is most useful as a list of differential diagnoses. In clinical practice, patients with various exclusionary conditions may also be diagnosed and managed as having CFS based on the physician's medical opinion.

Prevalence and Prognosis

Fatigue is a common complaint. Community-based epidemiological studies suggest that at any given time approximately 10% of women and 5% of men suffer from fatigue of greater than 6 months' duration. However, because CFS requires severe, medically unexplained fatigue that is not resolved by rest, cannot be explained by medical or psychiatric illness, and is accompanied by specific symptoms, CFS itself is far less common. Prevalence rates vary significantly across studies, probably as a result of differences in diagnostic criteria and experimental design. Nevertheless, it appears that 0.3 to 1.6% of the population meet criteria for CFS. In the largest community-based epidemiological study conducted to date, researchers at the Centers for Disease Control and Prevention (CDC) found that 2% of women and 0.9% of men met CFS criteria based on phone interviews. However, when carefully evaluated by a trained clinician, most of these individuals failed to qualify for CFS because symptoms had changed or a potential medical or psychiatric exclusion was identified. Based upon these careful assessments, the CDC now estimates the prevalence of CFS to be 235 per 100,000 adults 18 to 69 years of age, or 0.24%.

Traditionally the prevalence rates for CFS have been thought to be highest in middle- and upper middle-class White females. It is now clear that this reflects a bias in early studies that recruited patients from medical practices. Large community-based epidemiological studies in the United States indicate that CFS is equally or more common in African Americans, Hispanics, and Native Americans and among individuals who earn less than $40,000 per year. However, in all these groups, women are two to four times more likely than men to have CFS.

CFS is a chronic illness that waxes and wanes over time, and although patients report significant improvement, it is unclear if the illness completely resolves. Patients with CFS are strikingly disabled: Between 40 and 70% are unable to work or attend school, and 93% report severe impairment in their ability to perform daily life activities. Some evidence suggests that patients who develop CFS suddenly may have a better outcome than those who develop the illness insidiously over time.

Etiology

Despite several decades of research, the etiology of CFS remains unclear. In any potential etiological domain, studies reporting positive findings are nearly always counterbalanced by studies that are negative. Nonetheless, tentative conclusions can be drawn concerning physiological systems that may be abnormal in at least some patients with CFS. It is important to remember, however, that it remains unknown whether any given abnormality represents a cause or a consequence of CFS.

Early etiological theories of the disorder focused on the immune system and infection with Epstein Barr and other latent viruses. Although cases of CFS may follow such infections, it is clear that specific viral infections are not a primary cause of the disorder. A variety of immune system abnormalities have also been reported, including decreases in natural killer cell activity and increases in proinflammatory cytokines, especially in patients with sudden-onset CFS. A recent study indicated that CFS patients have increased delayed type hypersensitivity reactions, suggesting an abnormality in T-cell-mediated immunity.

Patients with CFS also may exhibit decreased activity of the hypothalamic-pituitary-adrenal (HPA) axis, the body's primary stress response system. Several studies report decreased levels of circulating cortisol and decreased adrenocortical reserve. Concordant with this observation, one study reported that CFS patients demonstrate adrenocortical atrophy on CT scan. In addition to decreased functioning, the HPA axis has also been reported to lose its normal circadian rhythm in CFS patients. Clinical improvement has been associated with normalization of this rhythm.

Other physiological abnormalities have been reported in patients with CFS. Many patients with CFS complain of unrefreshing sleep. In keeping with this, fibromyalgia, which has symptoms that overlap with those of CFS, has been characterized by an increase in awake-state (alpha) brain rhythms during deep (stage 4) sleep. It has also been reported that abnormal autonomic nervous system functioning may be common in patients with CFS, based on the fact that at least some CFS patients demonstrate orthostatic intolerance when subjected to tilt table testing. Con-

versely, patients with postural orthostatic intolerance syndrome often manifest symptoms similar to those seen in CFS. Alterations in central nervous system serotonin, arginine vasopressin, and growth hormone have also been described.

Finally, psychological and stress-related factors have been associated with CFS. Many patients report an increase in life stress in the year prior to disease development, especially when the illness develops slowly. Recent work with identical twins suggests that patients with CFS are more affected by similar levels of somatic distress than are genetically identical but unaffected persons.

Treatment

Numerous treatments have been applied to CFS patients, with various results. Those with the best experimental data to support efficacy include graded exercise training and cognitive-behavioral therapy. Low-dose corticosteroids have been reported to improve symptoms in two studies. Trials of antidepressants have yielded a confusing welter of positive and negative results, but in general these agents appear to be significantly less effective for CFS than for mood or anxiety disorders. Other CFS treatments with at least one positive study to their credit include growth hormone, selegiline, immunoglobulin, ampligen, nicotinamide adenine dinucleotide (NADH), and omega-3 fatty acids. Although treatments may ameliorate symptoms, to date, none will resolve the disorder.

CLINICAL GEROPSYCHOLOGY

Overview

Clinical geropsychology is a subfield of psychology concerned with the psychosocial issues that affect the mental health and quality of life of people aged 65 and older and their caregivers. Clinical geropsychologists provide assessment and treatment of a complex set of problems among older adults in a wide variety of service settings such as medical clinics, community mental health clinics, assisted living facilities, and nursing homes.

Clinical geropsychology has grown substantially in the past 20 years, a timely increase given that recent population demographic estimates suggest that in the year 2030, 20% of the U.S. population is expected to be 65 years and older. In recent years, economic forces such as new opportunities for Medicare reimbursement for psychological services have also served to increase practice in geropsychology. Unfortunately, the burgeoning numbers of older adults in American society suggest that without a substantial increase in both the availability of, and interest in the pursuit of, geropsychological training, increased funding for psychological treatment research, and insurance parity for mental health services, the future mental health needs of many older adults may not be adequately met.

Mental Health In Late Life

Epidemiological studies have found that mental health problems such as depression are not a natural consequence of growing older. However, there are a number of challenges that occur primarily in later life and that may increase the disability and burden of mental health problems among the elderly. For example, serious medical illnesses and related functional decline are much more common in later life. Bereavement related to the loss of a spouse, although not uncommon among younger adults, is very common among married or partnered older cohorts. Likewise, the functional and emotional challenges to individuals and family members posed by dementing illnesses such as Alzheimer's disease largely occur during later life.

Stressful life events and hassles, medical illness, physical and functional decline, and decreasing social activity are all associated with causing or worsening a wide variety of mental disorders among older adults. When mental disorders, medical illness, and functional decline co-occur, older adults face a greatly increased risk of hospitalization and placement in long-term care facilities. It is important to note, however, that older adults vary substantially in terms of their mental and physical health, physical abilities, level of cognition (e.g., memory skills), independent living skills, community functioning, family and social relationships, and overall well-being. Some older adults are relatively healthy and active well into their 80s and 90s.

Assessment

Diagnostic and functional assessments provide a comprehensive understanding of older adults' needs and typically include critical information about psychiatric diagnosis and social and environmental factors that influence older adults' emotions and behavior. Quality assessments are needed to ensure that an appropriate intervention is chosen for treatment. Geropsychologists use standardized interview and self-report instruments that have been specifically designed for use with older adults to diagnose psychiatric disorders such as depression, anxiety, and Substance Abuse. In the case of dementing illnesses such as Alzheimer's disease, which affect approximately 50% of older adults over the age of 85, psychological assessment evaluations determine the extent of problems with functions such as attention and

memory skills and the extent to which the disease has adversely impacted important day-to-day activities such as self-care, household care, financial management, driving skills, and social activities. Evaluations of the possibility of elder abuse by caregivers and assessment of the medically ill older adult's competence to make legal, financial, and medical decisions are also elements of practice that may fall under the scope of the geropsychologist.

Treatment of Late-Life Psychopathology

Many older adults with recognized mental health problems are prescribed medications by their treating physicians in primary care settings. However, a substantial body of geropsychotherapy research over the past two decades has resulted in the development of a variety of psychological treatments for some of the most common mental health problems faced by older adults. Clinical geropsychologists provide psychotherapy or so-called talking treatments for these problems. For example, a number of theoretically and practically distinct treatments (e.g., psychodynamic or insight-oriented, cognitive-behavioral or learning-based, interpersonal therapy) have been found to be effective in the treatment of depression among healthy older adults. Psychological treatments are also available for anxiety disorders and sleep disorders such as Insomnia. There is a nascent but growing body of clinical research for older adults with Schizophrenia and older adults who engage in health-damaging substance abuse behavior (e.g., alcohol abuse). The few medical and psychosocial treatments currently available for dementia are focused on managing problem behaviors such as wandering and agitation. New treatments currently under development focus on managing the emotional problems such as depression that often co-occur with dementia. Given the literature documenting the substantial negative emotional and health impacts associated with caregiving for an older adult suffering from a dementia, geropsychologists may also administer psychological interventions to improve the functioning and emotional well-being of family caregivers. Effective caregiver interventions may serve the beneficial purpose of delaying the older adult's entry into a long-term care setting.

Future of Clinical Geropsychology

The future of clinical geropsychology depends on the achievement of a number of tasks, such as increasing the number of qualified clinicians, expanding the number of available treatments for late-life psychiatric disorders, increasing funding and expanding access for mental health services for older adults, and figuring out how to make mental health interventions acceptable and easily available for as many older adults as possible. Prevention and treatment programs must be incorporated into the health care and community settings where older adults are already receiving services, as this may partly bypass the stigma that many older people currently associate with mental health treatment. Geropsychologist involvement in key public policy initiatives such as creating parity for mental health coverage in insurance plans may also lead to improved access to mental health services for older adults.

Future geropsychological research should focus on identifying factors associated with healthy and adaptive aging, characterizing late-life psychiatric disorders, and clarifying the differences between early- and later-onset disorders. Future psychotherapy treatment research should improve upon and expand the number of useful psychotherapy treatments for late-life mental health problems. Finally, in order to generate treatments for older adults whose well-being is most at risk, psychotherapy research should extend its focus beyond diagnostic categories, to older adults whose mental disorders and symptoms place them most at risk for disabling functional impairment.

CLINICAL GRADUATE TRAINING IN PSYCHOLOGY

Clinical graduate training has undergone many changes during the past 50 years. The American Psychological Association (APA) responded to an increased need for psychological services after World War II by developing a model curriculum for the training of psychologists. In 1948, the APA granted accreditation to 35 doctoral programs. In 1949, the Boulder Conference promulgated a scientist-practitioner model for instruction. Although many institutions continue to adhere to this model, the 1973 Vail Conference proffered a scholar-practitioner approach that ultimately led to the granting of the Doctor of Psychology (Psy.D.) degree. This model emphasized practice-related skills with less focus on the production of research. U.S.-trained doctoral-level applied psychologists may have the Ph.D., Psy.D., or Ed.D., and all complete a 12-month applied internship as an integral component of their education. Many new graduates elect to complete postdoctoral training to specialize or enhance skills.

New Mexico became the first state to pass legislation that grants psychologists the authority to prescribe psychotropic medication. As psychopharmacology becomes an aspect of psychological expertise, the type of graduate training psychologists undergo may significantly change. It is possible that an increased emphasis on the biological aspects of behavior and psychopharmacology may occur.

This may lead some departments to require natural science prerequisites for admission. However, if training to prescribe is limited to postdoctoral education, there may be little change in the graduate curriculum. The course work heavily emphasizing psychopharmacology would, in that model, take place only within specialty training after completion of the graduate degree.

The APA guidelines for professional psychology programs (APA, 1996) focus on student competencies. This requires doctoral programs and internship centers to determine the skills they want their trainees to demonstrate and to develop evaluative methodologies.

Competencies

Competencies are practical, flexible, observable, and measurable (Stratford, 1994). To be practical, a competency must consist of a manageable number of subskills. To be flexible, it must allow for a variety of approaches. This allows students to follow through with the task in a manner that best suits their development and the circumstances or that most effectively addresses the research topic.

After relevant skills are determined, a method of measuring designated target behaviors is developed. For example, competency in the administration of the Wechsler Scale may be verified by use of the Administrative Checklist for the WAIS-III (Sattler & Ryan, 2001). The competency approach understands that a minimal standard must be set and that, if that standard is not met, one is not considered competent (Fantuzzo, 1984).

Developmental Issues in Competency Assessment

Many (e.g., Hogan, 1964; Stoltenberg, 1981) consider the acquisition of psychotherapeutic skills and their evaluation from a developmental perspective. Novices need information and are learning to comprehend fundamental principles. Thus, entry-level skills are best evaluated by the use of tests (Chambers & Glassman, 1997).

Students who are more advanced can be assessed through simulation. This may entail an evaluation of the individual's breadth of knowledge as well as hands-on performance in scenarios that closely emulate actual practice. Training methods might include problem-based learning, close supervision in practica, and the writing of research proposals.

When students' competency levels will soon allow them to function autonomously, direct evaluation is required. This may involve research studies, record reviews, a portfolio approach, case presentations, or some combination of these (Chambers & Glassman, 1997).

Core Body of Knowledge

The APA (1996) criteria concerning the elements of psychological knowledge that should be acquired by students include the biological, cognitive, affective, and social aspects of behavior. Additional domains of study include the history of the field, psychological assessment, research methods, individual differences, ethics, human development, psychopathology, psychodiagnosis, intervention, cultural differences, and the attitudes that facilitate problem solving, scholarly investigation, and lifelong learning.

Building on a strong psychological knowledge base, the National Council of Schools and Programs in Professional Psychology (Peterson et al., 1991) proposed competency areas presented here in a modified form (Sumerall, Lopez, & Oehlert, 2000):

Relationship refers to the capacity to develop and maintain a constructive working alliance with clients.

Assessment is an ongoing, interactive, and inclusive process that serves to describe, conceptualize, characterize, and predict relevant aspects of a client.

Intervention consists of activities that promote, restore, sustain, or enhance positive functioning in clients through preventive, developmental, or remedial services. The concept of empirically validated treatments has gained acceptance, and a task force within Division 12 (Clinical) of the APA has published a listing of such interventions (Task Force, 1993).

Intervention competencies may be divided into those for individuals, couples, families, and groups as well as infants, children, adolescents, adults, and the elderly. They may be classified according to complexity or acuteness of the presenting problem. Areas to consider include dual diagnoses, cognitive impairment, social or familial impairment, chronic psychosis, and severe personality disorders.

Research involves a systematic inquiry that focuses on problem identification and the acquisition, organization, and interpretation of information pertaining to psychological phenomena. Students become involved in research early in the educational process and assist with ongoing studies prior to initiating the thesis or dissertation.

Education is the enhancement of knowledge, skills, and attitudes in the learner, whether a student, client, allied professional, or family caregiver.

Management includes activities that direct, organize, or control the services that psychologists and other professionals offer or render to the public.

Advanced clinical skills are areas of expertise represented by specialties such as neuropsychology, forensic practice, and, possibly in the future, psychopharmacology.

Ethics involves the acquisition of strategies for addressing conflicts in principle ethics (e.g., how one should act in specific situations; Meara, Schmidt, & Day,

1996) and virtue ethics (educating professionals to be a certain type of person (e.g., competent, honest, etc.).

Attitudes can refer to professionalism and professional development.

Summary

Graduate education in professional psychology involves training in a broad array of psychological skills, knowledge areas, and applied experiences. As the field matures, new clinical interventions, possibly including psychopharmacology, will be incorporated into the training students receive. The creation of new knowledge and the ability to evaluate and utilize research literature will continue to be an important component of graduate education.

CLINICAL JUDGMENT

Clinical judgment is the cognitive process by which a clinician estimates a clinically relevant parameter for an individual patient or client; it also refers to the product of that process (the parameter itself). Accuracy in clinical judgment is presumed to be acquired through experience and to be associated with expertise.

Although there are many parameters that a clinician might estimate, the two most important classes of parameters are, broadly speaking, probabilities of a clinical event and values for clinical states. Clinical probability judgment comprises judgments of probabilities in the absence of individuating information and judgments of probabilities conditional on individuating information. In several clinical fields, the clinical judgment of the probability of an outcome is referred to as the *index of suspicion* associated with the outcome.

In the first case, the clinician must estimate the likelihood of some outcome on the basis of his or her knowledge of and previous experience with the outcome (e.g., that a new patient will be schizophrenic or allergic to penicillin). In principle, the novice clinician ought to do this by retrieving information about the frequency of the outcome that he or she has learned during his or her clinical education, while the more experienced clinician is likely to treat the judgment as a pattern-matching task and assess the likelihood of outcomes on the basis of their similarity to prototypical outcomes with which the clinician has familiarity and whose relative frequency the clinician knows. In medicine, Geoff Norman, Georges Bordage, and Larry Gruppen have been influential in the description of the semantic and cognitive structures underlying these pattern-matching judgments.

The psychological literature, particularly the work of Daniel Kahneman and Amos Tversky in the 1970s and 1980s, suggests that probability judgments are often subject to systematic biases, particularly those produced by the availability heuristic (the probability of recent and memorable outcomes is overestimated). In medicine, students are often given maxims like "when you hear hoofbeats, think of a horse, not a zebra" to encourage them to consider common diseases before rare ones.

In the second case, the clinician is attempting to revise his or her belief about the patient's status on the basis of individuating information, such as patient history, physical examination, or diagnostic testing. For example, a clinical psychologist may wish to estimate the probability that the client is schizophrenic, conditional on the score of the client's Minnesota Multiphasic Personality Inventory (MMPI). Bayes' theorem is the normative model for revision of probability judgments on the basis of new evidence, but formal Bayesian calculations require the clinician to specify not only his or her prior belief about the patient's status but also the likelihood ratio associated with the individuating

information, and Bayes' theorem makes independence assumptions that can be difficult to meet in clinical practice. Hal Arkes and several other psychological researchers have characterized clinical judgment as insufficiently Bayesian and reported both inappropriate conservatism in judgments (failure to revise beliefs sufficiently) and inappropriate disregard for prior probabilities (resulting in too much revision). The use of pattern-matching strategies based on a representative heuristic (how representative the case is of the prototype) can also lead to systematic biases. However, it is unclear how frequently these biases impact clinical judgments in the real world and how important their impact is.

Probability judgments alone are rarely sufficient to make a clinical decision, because the values of a correct diagnosis, a correctly rejected misdiagnosis, a missed diagnosis (a false negative), and a false positive diagnosis are often different. Accordingly, the other major class of clinical judgments is estimations of the value that patients or clients will place on an outcome. Although clinicians can often directly ask their patients to evaluate the impact of outcomes on their quality of life, in many circumstances clinicians find themselves acting as surrogate judges of value as well as probability.

As with probability judgments, clinical value judgments have been shown to be susceptible to several systematic biases. Arthur Elstein and his colleagues have documented several of these biases since their research program began in the late 1960s. Most of these biases, however, are also at work in patients or clients making their own value judgments, and they are not specific to clinical judgment. Although some studies have demonstrated that surrogate clinical judgments are poor predictors of direct judgment by patients, other studies have found good correspondence between surrogate and personal values in some aspects of value judgment, such as the rate at which future events are discounted in evaluations.

Several approaches to the measurement of the quality of clinical judgment have been suggested. The most common is to measure calibration of probability judgments. In a well-calibrated clinician, events judged to have a given probability actually occur with that relative frequency. For example, events that the clinician considers 70% likely should actually occur 70% of the times that the clinician makes the judgment. Neal Dawson has reviewed three more sophisticated approaches: receiver operating characteristic curves, mean probability scores, and Brunswickian lens model analyses. The quality of clinical value judgments must usually be assessed by their association with direct judgments of outcome values by the patients or clients involved. Multiattribute utility approaches can also be applied to attempt to determine if the clinician places the same relative weights on the dimensions of the outcome that the patient or client does.

Because unaided clinical judgment may be subject to several systematic biases, many clinical areas rely on guidelines, scoring rules, or other algorithms as judgmental aids. These aids may call attention to important cues or dimensions to consider in the judgment, warn against the use of irrelevant cues, or even prescribe a formula for combining observed cues and prior beliefs to provide an estimate of the object of judgment. Research by Paul Meehl, Robyn Dawes, and other psychologists has repeatedly demonstrated that even simplified statistical prediction rules can outperform clinical prediction in a variety of situations. Although some guidelines have been successfully introduced in clinical fields, many are applied inconsistently or run afoul of practitioners' beliefs that their clinical judgment is likely to be superior to a guideline.

Alan Schwartz
University of Illinois, Chicago

COGNITIVE MAPS

A cognitive map represents the relative locations of points in space, making it possible for an animal to orient itself toward a point that has no distinctive cues. Tolman appears to have coined the term and to have applied it to maze learning in rats. His cognitive map hypothesis was tentatively supported by data from his laboratory, namely the sudden drop in errors with the initial introduction of a food reward in a previously explored complex maze and appropriate responding in so-called insight and alternative path studies. Similarly, Maier's three-table-reasoning problem assumed that a successful rat knew the position of each table with respect to the other two tables.

Later, Olton provided somewhat more convincing evidence for the hypothesis of cognitive maps. Using an eight-arm radial maze, Olton and associates studied spatial memory in the rat by removing the food pellet at the end of each alley once it had been visited on the trial. The rats soon learned, to almost an errorless level, to enter only an arm that had not been previously visited. Rats perform well with controlled odor cues or odor trails, go to the appropriate spatial location even when the maze is rotated, and do not learn fixed sequences that could function independently of spatial memories.

Morris tested the cognitive map hypothesis directly by requiring rats to locate a slightly submerged platform in a tank of water made opaque by adding milk. Once the maze is learned from the one starting point, the rat can be dropped into any point in the tank and it sets a course more or less directly toward the platform, as consistent with a cognitive map.

One animal that clearly has a cognitive map, one that may be superior to that of humans, is the chimpanzee. This was first observed by Tinklepaugh in his study of multiple

delayed response using 16 different containers situated as equally spaced pairs in a large circle. One member of each pair, on the left or the right, was baited while the subject (chimpanzee, human adult, or human child) watched. After a short delay, the subject was free to find the hidden object for each pair. Children did very poorly on this task, and chimpanzees were slightly superior to human adults, having a success rate of more than 70%, even when the baiting was done in a random fashion, which would seem to rule out unintentional cuing by the experimenters because they did not remember where things were either.

Birds also seem to have cognitive maps. For example, marsh tits exhibit good spatial memory for seeds that they have hoarded in a variety of cache locations. They also avoid earlier used but now empty holes. These memories probably reflect species-specific adaptations. The birds are very poor in finding seeds stored in holes by an experimenter, which rules out smell as a basis for detecting seed locations.

Bees clearly use landmarks around sources of nectar to locate the substance, but recent evidence suggests that this local map consists of route-based memories rather than a cognitive map of a familiar landscape, as with humans and other vertebrates. A study by Whishaw on latent learning in a swimming pool task raises questions about the rats' use of cognitive mapping, because of strong evidence for the use of associative processing.

Denny provides information on how cognitive maps are established. Visual recognition and ability to move about in a spatial layout were tested following single-route or multiple-route training of the space solely through kinesthesis (by means of blind hand movements among points on a plane). Single-route training, in spite of much more practice on the target route, failed to yield better learning of the route than multiple-route training and produced a much poorer cognitive map, as judged from kinesthetic and visual transfer tasks. Certain conclusions seem justified: (1) the more varied the initial experience, the more abstract and less egocentric (individual-referenced) the representation of space becomes, and (2) active experiencing of space produces a representation of the space as a coordinated whole—one that transcends the individual links (paths) between locations. The whole is known better than its parts.

COGNITIVE NEUROSCIENCE

The study of the neural basis of cognition, or cognitive neuroscience, has evolved rapidly in the last 10 years. In large part this has resulted from the parallel advances in imaging technology and raw computing power. Indeed, the exponential growth and concomitant movement of extraordinarily powerful computers to the desktop has made routine the analysis of large, complex data sets. Cognitive neuroscience is an enterprise that depends heavily on the use of modern imaging technologies such as positron emission tomography and functional magnetic resonance imaging (fMRI), and because of this reliance on technology, the ability to look noninvasively at the functionings of the human brain has only become possible very recently.

The fundamental goal of the cognitive neuroscientist is to understand the neural basis of the human mind. Historically, the mind had been thought to be separate from the body. Rene Descartes, the eighteenth-century French philosopher-mathematician, was perhaps the most vociferous advocate of mind-body dualism. The question of where the human mind, perhaps even the soul, resides has plagued humanity for at least as long as written records exist. Until recently, there was no reason to suspect that the mind might have components that were tied to the body. After all, this notion might be discordant with the belief of the immortality of the soul—if the body dies, then so does the mind. Descartes circumvented the problem by separating the mind from the body, and therefore the brain.

Mind-body dualism did not last long. Neurologists of the nineteenth century began to notice that patients with specific brain injuries, either from stroke or trauma, displayed consistent behavioral deficits. Pierre Paul Broca, a French neurologist, systematically described the effect of lesions in the left frontal cortex on language. Insightfully, he was the first to state that language was localized to the left cerebral hemisphere. This opened the door for an explosion of cognitive localization in the brain. In its extreme form, phrenology, every function of the human mind could be localized to some bump or valley in the brain (and skull). The use of brain lesions to deduce brain function subsequently became the predominant method for exploring the mind/brain for the next 100 years.

The lesion method truly was the first cognitive neuroscience technique. Its growth paralleled the recognition of other types of deficiency syndromes in medicine. The lesion method relied solely on the power of observation and a ready supply of patients with various types of brain injury. The history of the field is full of references to famous patients whose unfortunate circumstances led to some insight about the functioning of some particular brain region. Phineas Gage, perhaps the first famous patient, was a nineteenth-century railroad worker who had an iron rod accidentally driven upwards from just below his left eye out through the top of his skull. Remarkably, he lived for another decade, and his subsequent change in personality from a reliable and steady worker to a profane, erratic, and irascible man was aptly characterized by his physician at the time: "Gage was no longer Gage."

The father of modern psychology, William James, was

attuned to these advancements in understanding the brain in the late nineteenth century. Further evidence linking brain function to cognitive processing continued to amass. The observation that regional changes in cerebral blood flow were tied to mental function can be traced to the fortuitous discovery in a patient with an arteriovenous malformation in his frontal lobe. This patient (and his physician) noticed an increase in audible blood pulsation when performing mental calculation. This observation, that local changes in cerebral blood flow are linked to neural activity, underlies all of modern functional imaging techniques.

The parallel development of new imaging technologies with increased computational power in the late twentieth century resulted in the development of two new methods to study human brain function. Positron emission tomography (PET) developed as an outgrowth of autoradiography. Unlike its predecessor, PET could be performed without the requirement of sacrificing the animal. PET takes advantage of the fact that when a positron (a positively charged electron) encounters an electron, the two particles annihilate each other, and two high-energy gamma rays are emitted in exactly opposite directions. When a series of gamma-ray detectors are arranged in a ring, the origin of the particle can be computed. Positron emitters can be synthesized into common molecules, like water or 2-deoxyglucose, and when injected into a subject they can be used to map cerebral blood flow or metabolism respectively. Similarly, fMRI relies on the coupling of neural activity to local cerebral blood flow. Current thinking suggests that transient increases in neural activity result in a hyperremic blood flow response. Oxygenated hemoglobin and deoxygenated hemoglobin have different magnetic properties, and because the increase in blood flow results in a transient increase in the oxy-deoxy ratio, this can be detected with MRI. By rapidly acquiring MRIs while a subject is performing a cognitive task in the scanner, one can correlate the changes in blood flow to what the subject is doing.

Although PET and fMRI typically measure only relative changes in brain activity, through careful experimental design it is possible to isolate the neural circuits associated with specific cognitive processes. The basis for this is called *subtractive design*. When an experiment is designed with at least two cognitive conditions, one of which is a control state, the brain activity maps obtained during the control state can be subtracted from the brain activity during the condition of interest. In actual practice, a statistical test is usually performed instead of a simple subtraction, but the assumption is that whatever brain regions show different activity between the conditions represent the circuit associated with processing the extra information. It is critical that the control state be chosen appropriately. Otherwise, one might be subtracting cognitive states that are so different from one another that the assumptions of this method are violated. In particular, subtraction assumes that cognitive process behave linearly: that is, that processes can be added and subtracted without interacting with each other. This may be true under some circumstances, but not all.

In general, the subtractive approach to imaging has confirmed what was known from the lesion method, but recent advances in fMRI have allowed the description of more subtle processes. By presenting subjects with very brief stimuli, we can measure the cerebral blood flow response and correlate it with individual events. This goes beyond the subtractive approach, which often requires the subject to maintain a cognitive state for tens of seconds to minutes. Event-related fMRI measures the brain response on a scale less than a second, which is much closer to the time scale at which the brain operates. New computational algorithms are also revealing the complex correlations that occur between different brain regions, which begins to reveal the choreography of brain activity that must be the hallmark of cognition. With the combination of rapid imaging and new algorithms, perhaps the elusive goal of identifying the neural basis of the mind will be achieved.

COGNITIVE NEUROSCIENCE OF LEARNING AND MEMORY

Cognitive neuroscience approaches, with their focus on relating neural substrates to cognitive functions, have advanced our understanding of the neural basis of learning and memory. In turn, our understanding of the neural basis has informed the way we think about the functional organization of memory systems. One of the most prominent themes in cognitive neuroscience has been trying to understand which kinds of learning and memory are spared, and which are impaired, with damage to the *hippocampus* (a specialized brain structure in the medial temporal lobe).

We have known for many decades that the hippocampus plays a disproportionately important role in learning and memory, since Scoville and Milner (1957) presented the famous patient HM. HM had severe memory impairments following bilateral medial temporal lobe lesions that included the hippocampus. Despite these severe impairments, including the inability to learn all kinds of factual information (names, places, facts, etc.), HM was nevertheless able to learn to perform new tasks (e.g., tracing while looking into a mirror). Many different attempts have been made to precisely characterize what distinguishes these preserved learning abilities from those that are impaired (e.g., Squire, 1992; Schacter, 1987; Sutherland & Rudy, 1989; Cohen & Eichenbaum, 1993; Rolls, 1990). Many of these ideas emphasize a *procedural* (e.g., sensorimotor task

learning) or *implicit* (i.e., not explicitly verbalizable) aspect of preserved learning abilities, which is consistent with the data from HM.

Computational neural network models, which simulate cognitive functions using networks of neuron like processing units constrained according to known properties of different brain areas, have provided a more precise language for understanding the unique contribution of the hippocampus in learning in memory (O'Reilly & Rudy, 2001). These models show that there is a basic computational conflict between two essential kinds of learning: the ability to rapidly learn specific novel information without interfering with previous knowledge, and the ability to learn about the generalities or regularities of the environment. Therefore, it makes sense that two different brain areas should each separately achieve these learning objectives. Biological and behavioral evidence coincide with this computational argument in suggesting that the hippocampus is specialized for the rapid learning of specific information, while the cortex is better suited for learning generalities.

The computationally motivated division of labor between the cortex and hippocampus is consistent with recent data from individuals who suffered selective hippocampal damage early in life. These people were able to learn all kinds of general information (e.g., language skills, semantic knowledge about the world) and had IQ scores in the normal range, yet they suffered from the inability to rapidly encode novel information as measured by *episodic* memory tests (Vargha-Khadem et al., 1997). Note that these data violate earlier notions that hippocampal damage spares only procedural or implicit learning, whereas the computational notions based on underlying neural mechanisms provide a more general framework that encompasses these data.

The cognitive neuroscience–based theories can inform our understanding of performance on the kinds of basic memory tasks that psychologists have been studying for many years. For example, many are now arguing that recognition memory (the ability to recognize an item as having been recently studied or not) can be subserved by two different neural systems having different functional properties (e.g., Aggleton & Brown, 1999; Norman & O'Reilly, in press; Yonelinas, 2002). One of these systems is the hippocampus, which can provide an explicit *recollection* signal (i.e., recalling specific aspects of the study episode), while the other is subserved by cortical areas surrounding the hippocampus, which can provide an indistinct sense of *familiarity.* As recent brain imaging techniques (functional magnetic resonance imaging [fMRI], positron emission tomography [PET], and event-related potentials [ERP]) improve their ability to resolve active representations in various memory tasks (e.g., Buckner & Koutstaal, 1998; Henson, Rugg, & Dolan, 1999), we should be able to test even more sophisticated and nuanced theories of the cognitive neuroscience of learning and memory.

COGNITIVE PSYCHOPHYSIOLOGY

Cognitive psychophysiology is an interdisciplinary field overlapping psychology and physiology in which efforts are

made to solve the classical problem of "mind" through modern electronic technology. The primary thesis is that mental processes are generated when selective bodily systems interact and that they can be directly studied with sufficiently sensitive equipment. The bodily systems include the receptors (eyes, ears, etc.), central nervous system (principally the brain), skeletal musculature, autonomic system (the gastrointestinal tract, the cardiovascular system, etc.), and their neural interconnections. The field's interdisciplinary nature is exemplified by the presence of researchers from psychology, physiology, medicine, and biomedical engineering.

Approaches to the problem of mind, dating from the time of ancient philosophers, may be summarily classified as either *dualistic* or *monistic.* Traditionally, dualistic positions have been the most popular, even as they are today in everyday thinking. The basic assumption of dualism is that there are two kinds of entities in the world, those of a physical (material) and those of a mental (nonmaterial) nature; furthermore, in dualism only physical events are knowable by science. Monism, however, holds that the universe consists of only one kind of entity. The principal monistic position is that of strict materialism, which holds that there are only physical phenomena in the universe. According to materialistic monism, therefore, mental processes are physical phenomena generated within the body and can therefore be directly observed through scientific technology.

Contemporary Assessment of the Problem of Mind

In considering where in the body thoughts occur, objectivity demands that we avoid predisposing biases and consider that any bodily system might serve some cognitive function until empirically established otherwise. However, the reactions of these systems are often so subtle that they are referred to as *covert* (versus *overt*). Covert reactions are such small-scale bodily processes that they cannot be observed with the naked eye; hence they must be amplified in the laboratory to be studied, as in the case of brain waves or heart activity.

Cognitive psychophysiologists, specializing in different bodily systems and using extremely sensitive procedures, have now been successful in measuring covert reactions *throughout* the body during cognitive activities. Furthermore, it has been established that these events occur in close temporal proximity to one another and are systematically (often causally) related. The conclusion is inescapable that widespread covert reactions in the receptors, brain, muscles, and autonomic system are intricately linked through complex neuromuscular circuits that have cybernetic (feedback or servoloop) characteristics.

The Transition From Mechanical to Electronic Methods

Around the turn of the twentieth century, researchers eagerly attempted to construct "thought-reading machines" with what tools were then available. With the advent of the vacuum tube, these crude mechanical methods gave way to the sensitive electronic techniques that were critical for the advancement of cognitive psychophysiology. Thus, about 1921, primitive electromyographs for recording electrical components of muscle activity became available. The first recording of electroencephalograms was by Hans Berger in 1929, empirically establishing that the brain generates electrical signals (although Berger's findings were greeted with skepticism for many years). The galvanic skin response and other measures of autonomic activity during emotion had been initiated in the late nineteenth century (especially with Feré in 1888); such autonomic measures were important in the early development of cognitive psychophysiology, as they continue to be today.

There are four essential features of a cognitive psychophysiological laboratory for electrically studying covert bodily events: (1) *sensors,* usually electrodes placed over the brain and on the surface of the skin to detect electrical components of neural, muscular, and glandular phenomena; (2) *amplifiers,* which increase the amplitude of the body signal sensed; (3) *readout devices,* such as cathode ray oscilloscopes or recorders, which can display the covert body signals; and (4) *quantification systems,* which render numerical values for those signals.

A number of the more commonly measured psychophysiological events are classified in Table 1. The primary division is between *responses* of the muscular and glandular systems and *neurophysiological* processes of the central nervous system.

The first two response classes in Table 1, those of the skeletal musculature in the speech and somatic regions, are best measured electrically through electromyography. *Myo,* standing for muscle, and *graph,* for writing, form the term for recording electrical components of muscle activity.

Covert eye behavior, the third response category in Table

Table 1. Covert Psychophysiological Events in Humans

I. Covert Responses (muscular and glandular events)
   A. Covert speech responses: electromyographic measures from the tongue, lip, chin, cheek, laryngeal, and jaw regions
   B. Covert somatic responses: electromyographic measures of the skeletal musculature from the fingers, arms, legs, etc.
   C. Covert eye responses, principally through electrooculography
   D. Covert autonomic responses
      1. Cardiovascular measures such as heart rate, electrocardiogram, finger pulse volume, and blood pressure
      2. Visceral muscle activity principally from the intestines, as the electrogastrogram
      3. Electrodermal measures from the surface of the skin (galvanic skin response, skin conductance, etc.)

II. Neurophysiological Processes
   Electrical activity from the brain, recorded with electroencephalography, through signal averaging, yields average evoked potentials, and the contingent negative variation.

1, is typically recorded through electrooculography, where *oculo* refers to the eyes.

The last response class, that for autonomic behavior, consists of a variety of subcategories. Common autonomic components include: (1) measures of heart (cardiac) activity through electrocardiography; (2) activity of the intestinal portion of the gastrointestinal tract, which, when electrically recorded, yields the electrogastrogram; and (3) electrodermal measures of skin (dermal) activity, most prominently the galvanic skin response measured with the psychogalvanometer.

The second major category in Table 1 is for electrical signals from the brain. These include such well-known events as alpha waves (large amplitude, cyclical waves) and beta waves (lower in amplitude than alpha waves but greater in frequency).

With the entrance of the small electronic computer into the laboratory, however, it became possible to *average* brain waves to expose intrinsic signals not discernible in the raw traces.

Direct Electrical Measurement of Mental Processes

Individual experiments have established that each of the events specified in Table 1 occurs during cognitive experiences (although the grand experiment of simultaneously recording all those measures has not been attempted). The various mental events are *similar,* then, in that they all involve covert activities throughout the body, including the brain.

The *unique* mentalistic terms for mental events exist because the experiences occur under different environmental and organismic conditions. Night dreams, daydreams, and directed rational thought all differ, for instance, because of the degree to which they are influenced by environmental input. During "sleep thoughts" or images of night dreams, most environmental stimulation is physiologically shut off, apparently at the reticular activating system. Consequently, the mental activity of dreaming is chaotic, since it is not directed by external reality, or, as one psychiatrist put it, a night dream allows us all to go safely insane for a brief period of time. Similar mental processes occur in the daydream, but they are partially influenced by the external environment. During directed problem solving, rational thought processes are largely controlled by repeated reference to the environment.

Hallucinations—false perceptions that the patient confuses with real ones—are akin to night dreams in that they are controlled by internal stimuli, although they are mistakenly ascribed to external forces. Neuromuscular circuits that generate visual hallucinations presumably include the occipital lobe at the back of the brain and the eyes. Auditory hallucinations are similarly thought to be generated when auditory and linguistic regions of the brain interact with muscles of the ears and speech. Auditory hallucinations, for instance, seem to be produced when the patient subvocalizes, as indicated by auditory and electromyographical recording of covert speech (Figure 1).

Figure 1. A sample tracing of the report of a hallucination. The 2-sec intervals before and after the report are marked on the event line at the top. Next in order are the pneumogram, arm electromyogram, chin electromyogram, tongue electromyogram, and the sound record. The increase in chin electromyographic activity and in subvocalization (bottom trace) coincide with the hallucinatory experience.

Auditory components of night dreams are apparently generated by neuromuscular circuits like those for auditory hallucinations. Figure 2 illustrates small-scale, rapid covert muscle activity in the lips and chin when one experiences conversations in dreams. These covert speech responses are not present during visual dreams or nondreaming periods.

Deaf individuals who are not proficient in oral speech use dactylic ("sign" or "manual") language for communication. The muscles for the fingers therefore are the locus of

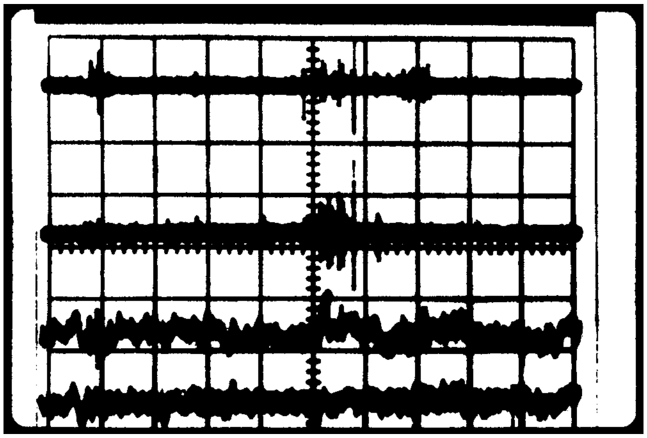

Figure 2. Illustration of signals during a conversational dream. From the top down, the signals are lip electromyogram, chin electromyogram, horizontal eye placement, and frontal electroencephalogram. Amplitude for the top three traces is 50 μV/division, and 100 μV/division for the electroencephalogram. Time is 1 sec/division.

their linguistic response mechanisms. For them, consequently, the speech musculature is not engaged during thought. Instead, they make covert finger responses when thinking. In addition, individuals who are proficient in both oral and manual language processes engage both the speech musculature and the fingers covertly during thought.

Technological Consequences

As from all scientific fields, a number of practical applications flow from cognitive psychophysiology, perhaps the most important being principles for self-regulation. As one continuously meets the stresses of life, there often eventuates some bodily malfunction. The primitive reaction of the body to stress is characterized as the startle reflex, a major component of which is the tensing of the skeletal musculature for fight or flight. Chronic states of excess tension throughout the skeletal musculature can result in two classes of bodily malfunctions: (1) psychiatric difficulties such as anxiety states, phobias, and depression; and (2) psychosomatic maladies such as ulcers, headaches, spastic colon, and elevated blood pressure. The original and apparently most effective method for alleviating these tension maladies is progressive relaxation, developed by Edmund Jacobson from 1908 on. In progressive relaxation one relaxes the skeletal muscle system, which in turn produces a state of tranquility throughout the central and autonomic nervous systems. Jacobson has shown that habitual relaxation can thereby alleviate many psychiatric and psychosomatic maladies such as those mentioned previously. However, perhaps the prophylactic application of progressive relaxation has even greater beneficial consequences. For this purpose Jacobson has advocated that tension control be universally taught to children while in the primary grades.

Another prominent method aimed at the development of self-regulation is biofeedback, in which internal processes are transduced to make them publicly observable. The strategy is to monitor and thus control such internal events as brain waves, muscle signals, and electrodermal responses by visually observing them as on a cathode ray oscilloscope or by hearing them through an external speaker. Biofeedback holds considerable promise for helping us to better understand our internal world; much research is currently in progress in this important area. There are, however, difficulties in its clinical application, such as the dependency of the learner on a biofeedback signal. Consequently, if the desired changes in behavior occur in the clinic, they may not be lasting and generalized to the patient's everyday world. Nevertheless, a revolutionary consequence of biofeedback and progressive relaxation is that they provide the opportunity to study a person's internal world, just as classical psychology has concentrated on our relationship with the external environment.

Another application has been in the understanding of reading and of the teaching of silent reading. It is a common myth that subvocalization—or, more technically, covert speech behavior—retards reading proficiency. Popular speed-reading courses, for instance, seek to increase reading rate by short-circuiting the speech musculature. Some teachers have attempted to prevent subvocalization by taping lips or filling the mouths of pupils with marbles, by wrapping the tongue around a pencil, and so forth. However, such efforts to inhibit subvocalization are futile, for the speech musculature still responds during silent reading even when so inhibited. The empirical generalization is that covert speech behavior occurs in all silent readers and is necessary for comprehending what is being read. Actually, as the reading rate becomes faster, the amount of covert speech behavior does not *decrease,* but *increases.* However, if speech muscles are well relaxed during reading through progressive relaxation, the reader fails to understand the meaning of the text. The implication for teachers, therefore, is that they should not tamper with the child's subvocalization, for the child needs to subvocalize while reading. Actually, subvocalization becomes naturally reduced over time, although it still persists in the adult at a very reduced level.

Lie detection, or more precisely the detection of deception, is a widespread application for espionage purposes, for the identification of criminals, and even as a criterion for employment. The polygraph, which relies heavily on cardiovascular measures, is the most widely used instrument for these purposes. Unfortunately the traditional polygraph, like newer variations of lie detectors such as the psychological stress evaluator and the voice stress analyzer, does not have sufficient validity to justify its standard use. However, techniques and principles are available within the field of cognitive psychophysiology to develop successful deception detection systems, and these systems will undoubtedly be made.

COGNITIVE THEORIES OF EMOTION

Theories of emotion try to explain how emotion is aroused, how it produces physiological changes, and how one emotion differs from another. The answer to the first question distinguishes cognitive theories from other theories of emotion.

Theorists of all persuasions usually agree that anger, fear, or both are aroused when a situation is interpreted as annoying and/or dangerous. Many insist that such arousal is programmed into the nervous system during evolutionary prehistory and serves biological survival. For cognitive psychologists, every emotion is aroused by knowing something and appraising it. No doubt, some appraisals are preprogrammed: Infants like anything sweet the first time they taste it. However, older children and adults appraise what they encounter not only as it affects their bodily well-being but also as it affects them as persons. The child is angry when teased by buddies; the young man, when his pals show him up before his girlfriend. If emotions depend on appraisals, there will be as many different emotions as there are different appraisals. Emotions may be classified, but they need not be derived from one another.

Not surprisingly, cognitive theories have a long history. In the third century B.C., Aristotle suggested in his *De Anima* (*About the Soul*) that human beings and animals can make sensory judgments (through what he called the *vis estimativa*) of things as being good or bad for them; this estimate arouses an emotion, liking, or dislike. Thomas Aquinas, in his *Commentary,* followed Aristotle in this explanation of emotional arousal.

Descartes insisted that all emotions are aroused directly by exciting the "animal spirits," or by arousing inherent reflex actions together with the physiological changes necessary for survival—a notion shared by Darwin. William James and Carl Lange later reversed the commonsense view that emotion produces bodily changes, by insisting that bodily changes follow directly on the perception of the exciting object: Our sensation of these changes *is* the emotion.

The James-Lange theory of emotion was accepted unquestioningly and soon fatally reduced the interest of academic psychologists in the analysis of emotion.

To say that some situations arouse hereditary patterns is no solution. Fear or anger may arouse flight or attack, but both still depend on a realization that something is threatening or annoying, which is an appraisal, however rudimentary.

M. B. Arnold introduced the notion of appraisal into academic psychology. She defined emotion as "a felt action tendency toward anything intuitively appraised as good, or away from anything intuitively appraised as bad for me here and now," which is "accompanied by a pattern of physiological changes organized toward a specific kind of approach or withdrawal." Arnold distinguished a few basic emotions, simple reactions to the appraisal of basic situations: liking (love), dislike, desire, aversion, joy, sorrow, daring, fear, anger, hope, and despair.

In her book *Emotion and Personality,* Arnold pointed out that emotions depend not only on the intuitive appraisal of something as "good or bad for me," but also on the spontaneous appraisal of possible responses as suitable or unsuitable. Something threatening may be seen as difficult to escape and so arouses fear, or it may be appraised as something that can be anticipated by bold action and so is overcome by a daring attack. Arnold emphasized that the intuitive spontaneous appraisal is supplemented by a deliberate value judgment, at least in the older child and adult, just as sensory knowledge is complemented by conceptual knowledge. Because we use intuitive and reflective appraisals concurrently, even our intuitive judgments generating emotion can be educated. Because the person is a unit, every reflective value judgment will be accompanied by an intuitive appraisal. Value judgments are seldom if ever coldly objective: What is valued, attracts. Hence emotions can be socialized, influenced by social attitudes and customs.

Like other cognitive theorists, Arnold recognizes the importance of the physiological changes that accompany emotion. When these changes are felt, they are again appraised and may either reinforce or change the original emotion. When a person appraises an increased pulse rate during fear as indicating heart disease, the original fear is now overlaid by a fear of illness. By definition, heart disease weakens the body. The fear aroused by the increased pulse rate then dictates the appraisal that, being ill, one will not be able to cope with the situation, which increases the original fear.

Important research in emotion is reported by Richard Lazarus and his coworkers. These scientists make appraisal the cornerstone of their theory of emotion. Lazarus suggests that each emotion is based on a particular kind of cognitive appraisal accompanied by motor-behavioral and physiological changes. He distinguishes primary appraisal, secondary appraisal, and reappraisal. The secondary appraisal is an evaluation of a person's relation to the environment and so leads to an altered emotional response. Reappraisal can occur as a simple evaluation of the significance of this altered relation to the environment, or it may be a psychological attempt at coping with stress. Such a reappraisal is not necessarily based on factual information; it can be an attempt to look at the situation from a more congenial point of view. In Lazarus's terms, it may be a "defensive reappraisal." A reappraisal may also be an attempt at coping when direct action is impossible.

Lazarus and his associates found that the appraisal of a situation and therefore a person's emotional reaction could be manipulated experimentally. Before they showed a harrowing subincision film to the experimental subjects, they read a passage to one group that described the painful procedure at length, and they told another group that the boys in the picture were willing to undergo this initiation ritual and were proud of their stoic endurance. To a third group, finally, they gave intellectualizing informa-

tion that emphasized the anthropological significance of the ritual. The first group was strongly affected by the film, while the other two groups remained comparatively unaffected.

Although the influence of cognition on appraisal is well documented, the distinction between intuitive and reflective appraisal is more difficult to substantiate. In his article "Feeling and Thinking: Preferences Need no Inferences," R. B. Zajonc pointed out that the notion of the primacy of feeling has languished since Wundt's time. In cognitive psychology it has been replaced by an information-processing scheme in which an affective reaction occurs only after considerable processing. Hence major works on cognition disregard affect or feeling and concentrate exclusively on cognitive processing. Yet, says Zajonc, "affect . . . is the major currency in which social intercourse is transacted." Hence, "to arouse affect, objects need to be cognized very little, in fact, minimally." In recall as in perception, the affective reaction is the first element to emerge. As Zajonc points out, although affect may mark the end of considerable cognitive activity (in listening to a joke, for instance), this need not imply that cognitive activity is a necessary component of affect.

According to Zajonc, there is a separation between affect and cognition. Judgments of similarity and judgments of preference have different dimensions. Early in the twentieth century, T. Nakashima reported in his "Contribution to the Study of Affective Processes" that judgments of pleasantness and unpleasantness are independent of sensory qualities and so cannot be mediated by them. Aesthetic judgments and preferences of all kinds do not depend on cognitive analysis. Experimental investigations have shown that judgments of like and dislike are made and recalled with great certainty, while judgments that a given stimulus word is new or a repeat are made with noticeable uncertainty. Hence Zajonc concludes that the perceptual process, starting from sensory experience, arouses first an unconscious affective reaction, and next produces the recognition of familiar features (also unconscious) before the reflective cognitive processing begins.

We may conclude that Zajonc has exposed a chink in the armor of cognitive psychology. Thinking and reflective judgment seem to depend as much on affect as on sensory experience. Because affect is a conscious experience of attraction/repulsion that is not generated by a reflective value judgment, it must be aroused by the spontaneous (unconscious) appraisal of good/bad objects and suitable/unsuitable responses. Emotions are usually accompanied by reflective judgments, can themselves be appraised as suitable/unsuitable, and can be changed by corrective experiences but rarely by reflection or persuasion.

M. B. Arnold

COGNITIVE THERAPY

Definition

Cognitive therapy is a psychotherapeutic approach that teaches individuals that their interpretations of situations influence their emotions, physiological reactions, behaviors, and motivations. Cognitive therapy is a time-effective, structured, collaborative form of treatment that utilizes psychoeducation and psychological skills acquisition. Treatment focuses on helping patients to recognize thematic biases in their thinking; to generate alternative, adaptive viewpoints; and to use new cognitive, behavioral, and experiential strategies to improve mood and enhance problem-solving skills.

History

Aaron T. Beck developed cognitive therapy starting in the early 1960s. While empirically testing Freud's "anger turned inward" theory of depression, Beck instead found that depression involved a negative bias in thinking that often led patients to feel despondent and hopeless. Through clinical observations and research, Dr. Beck refined his cognitive theory of depression and developed techniques (e.g., Socratic questioning, hypothesis testing, cognitive reevaluation, behavioral experiments) to treat patients by modifying their biased thought processes. Beck's developing theory was influenced by ego-oriented psychodynamic psychotherapy (Adler, 1936), developmental cognitive psychology (Piaget, 1954), personal construct therapy (Kelly, 1955), social-learning theory (Bandura, 1977), behavior therapy (Mahoney, 1974), and the phenomenological school of psychology (Frankl, 1985). Beck integrated these diverse approaches into a powerful, new clinical methodology.

Although initially developed as a treatment for unipolar depression (A. T. Beck, Rush, Shaw, & Emery, 1979), cognitive therapy subsequently has been applied to a wider range of psychological disorders (e.g., personality disorders), daily living difficulties, medical problems, and other clinical populations. Cognitive therapy can be used in individual, couples, family, and group formats, with adults, adolescents, and children.

Theory

According to the cognitive model, negatively biased perceptions adversely affect mood and behavior. For example, an individual suffering from depression may experience automatic thoughts centering on self-criticisms or hopelessness about the self, the world, and the future (the *cognitive triad;* see A. T. Beck et al., 1979). These automatic thoughts may demoralize the patient, leading to inertia and a worsening condition, rather than to improvement through active coping. In addition to being identifiable by their *contents,* cognitive biases can be addressed and studied in

terms of their *process.* An example is *fortune telling,* in which the individuals assume they know that the outcome of an event necessarily will be negative. This may lead them not only to be pessimistic, but also to prematurely give up trying to attain the goal. This unfavorable outcome reinforces the negative belief, thus causing a vicious cycle that solidifies the emotional distress.

Automatic thoughts are theorized to be produced by more basic, fundamental, all-encompassing beliefs called "negative schemas" (Young, 1999). For example, an individual with an *incompetency* schema, upon being presented with a difficult task, may feel defeated, hopeless, and dysphoric even before trying to accomplish the task. In order to cope with the activation of this core negative schema, the individual develops compensatory behaviors, such as procrastination or other forms of avoidance. Sometimes these compensatory strategies can shield an individual from immediate distress, but more commonly they grow to cause their own set of difficulties. It is at this point that people typically decide that they need to seek therapy. A specific treatment plan is then developed from a conceptualization of the patient's automatic thoughts, underlying schemas, and compensatory strategies (J. S. Beck, 1995). Following this, realistic goals are set and are pursued via the use of individually tailored interventions.

Clinical Applications

Patients are taught to systematically examine and modify distorted thinking to gain a more objective and manageable view of their problems. Therapists conduct a comprehensive diagnostic evaluation and formulate a cognitive conceptualization (Persons, 1989) that is continually reshaped by new data throughout treatment. From this, the treatment plan and goals are set, pursued, and evaluated periodically.

An agenda is set each session and includes assessing the patient's mood, reviewing the main points from the previous session as well as the homework assignment, applying new cognitive and behavioral skills to ongoing issues and goals, summarizing the main ideas from the present session, getting and giving feedback about the session, and collaboratively generating ideas for new homework assignments. The therapist and patient collaborate to understand the patient's worldview and empirically evaluate specific target areas (e.g., social avoidance, procrastination, impulsivity). Cognitive therapists use a variety of cognitive, behavioral, and experiential interventions to monitor, test, and modify problematic beliefs and their concomitant emotions; to strengthen problem-solving skills; to replace compensatory behaviors with more adaptive strategies; and to develop an adaptive coping repertoire. Homework is assigned to reinforce work done in session, apply therapy lessons to the outside world, and design behavioral experiments for examination in the next session. Cognitive therapy patients learn important skills that maximize long-term maintenance of therapeutic gains.

COGNITIVE TRIAD

According to cognitive theory, many of the disturbances associated with depression result from the activation of a set of cognitive patterns that forces the individual to view his or her situation in an idiosyncratic, negative, and pessimistic way (Beck, 1967, 1976; Clark, Beck, & Alford, 1999). This set of negative cognitions is referred to as the *cognitive triad,* as it consists of thought patterns about the world, the self, and the future. The cognitive triad remains active in depressed individuals because such individuals selectively and inappropriately interpret experiences as being negative in some substantive way. Typical cognitions of depressed individuals show a variety of deviations from logical thinking, including making arbitrary inferences of negative meaning, selectively focusing on negative events, overgeneralizing from one negative experience, employing dichotomous thinking, and catastrophizing. As a consequence of these errors in information processing, the patient automatically makes negative interpretations of situ-

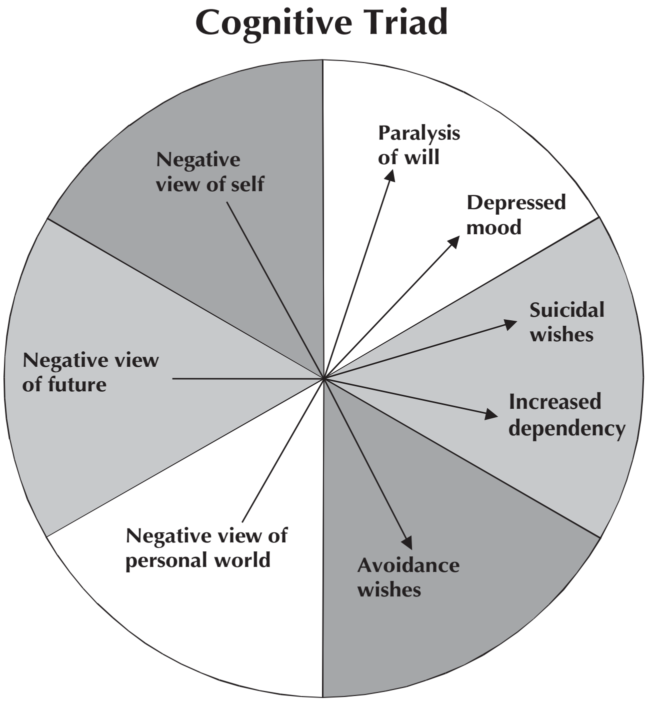

Figure 1. Cognitive triad.

ations even though more plausible explanations are readily apparent. The continued activation and dominance of the negative cognitive triad leads to other phenomena associated with the depressive state, such as sad affect and the lack of motivation.

Negative View of the Personal World

The first component of the cognitive triad (Figure 1) is the tendency of the depressed individual to interpret ongoing experiences in a negative way. Interactions with the environment are often misinterpreted as representing some form of defeat or deprivation. Automatic reactions to problems or difficulties are likely to be thoughts such as "I'm beaten," "I'll never be able to do this," or "I'm blocked no matter what I do." Any problem seems insoluble, and any delay in reaching a goal seems indefinite. For example, a depressed woman who had some difficulty finding a pencil in her purse immediately had the thought, "I'll never be able to find it." She experienced a strong sense of frustration even though she was able to find it in a few seconds.

Many patients with depression are particularly prone to react to achievement-oriented situations with a sense of failure or to make negative attributions whenever they are in a competitive situation. One patient had the highest standing in class, but whenever the teacher called on another student to answer a question, the patient thought, "He doesn't really think I'm smart or he would have called on me." If the professor complimented other students, the patient would have the thought that the professor had a low opinion of him.

Making comparisons with other people is especially likely to activate feelings of dissatisfaction and deprivation. Many depressed patients have thoughts such as "I don't have anything" when a friend acquires something new. In addition to feeling deprived, the depressed patient is prone to interpret comments from others as devaluing and is likely to read insults, ridicule, or disparagement into what other people say. In summary, the world of the depressed individual is filled with themes of defeat, deprivation, and devaluation.

Negative View of the Self

Depressed patients not only interpret their experiences as negative, but they devalue themselves as well. If a depressed individual does not do as well as expected on a test or a business venture, a likely immediate reaction is to think of himself or herself as ineffective and undesirable. A striking feature of the depressed patient is the tendency to overgeneralize from a particular incident. A student who had difficulty getting a date on a single occasion thought, "I must be repulsive to girls." A highly successful businessman who made one transaction that lost money became obsessed by the idea that he was stupid. A mother whose child was untidy on one occasion thought, "I'm a terrible parent."

Depressed patients often see themselves solely in terms of their deficiencies. Further, these negative self-evaluations are usually associated with self-rejection. Patients often will not only see themselves as inferior, but will criticize, reproach, and castigate themselves for being so inferior. Thoughts of ineffectiveness, inferiority, and inadequacy abound in individuals with depression.

Negative View of the Future

Depressed patients often show considerable preoccupation with thoughts about the future, and these ideations may occur in the form of pictorial fantasies or obsessive ruminations. Such thoughts have a negative cast and are usually an extension of the patient's view of the present state, often to the point that the patient sees no possibility for improvement. If patients regard themselves as currently deprived, immobilized, or rejected, then they are likely to visualize a future of continual deprivation, immobilization, or rejection. Not only are long-range forecasts pessimistic, but short-term predictions are similarly negative. When contemplating whether or not to perform a task, they predict that they will make a mess of it. When a suggestion is made that they engage in an ordinarily enjoyable activity, they assume they will not have a good time. One patient, for example, frequently had elaborate fantasies of failure before engaging in any activity. When driving to the psychiatrist's office for an appointment, she pictured herself making a wrong turn and getting lost. If she decided to go shopping, she imagined herself losing her purse or making the wrong

purchases. Like the present, the future is seen as containing one failure and defeat after another.

Implications

Identifying the automatic negative evaluations that depressed individuals make about their world, self, and future has significant implications for the diagnosis, assessment, and treatment of the condition. Cognitive therapists help patients identify such thoughts and then work to develop ways of challenging these faulty, overly negative evaluations. Such therapy has been demonstrated to be quite effective at alleviating symptoms of depression (Clark et al., 1999).

COMMUNICATION SKILLS TRAINING

Therapists of diverse theoretical positions have long realized that numerous clients with a variety of psychopathological complaints are deficient in interpersonal or communication skills. Persons diagnosed as schizophrenic, neurotic, or mildly mentally retarded, as well as alcoholics, those having marital difficulties, and parents with child management problems, have all been seen as having difficulties in interpersonal communication. In the period from 1970 to 1980, three major trends led to the increased emphasis upon communication skills training as an important therapeutic and preventive tool. The first and perhaps most important trend was the disenchantment of many psychologists and other therapists with the medical model of therapeutic intervention. As Goldstein has noted in *Psychological Skills Training* (1981), an increasing number of therapists turned to a different set of assumptions. Basic to this new approach is the assumption that the client is suffering from a skill performance deficit and that the role of the therapist is to teach or train the client to perform the requisite set of skills.

The second trend was the increasing application of behavioral strategies to the treatment of a diversity of behavioral problems. It was quickly recognized that before psychiatric clients could be deinstitutionalized or normalized they would have to learn an extensive array of communication skills, such as conversational skills and job acquisition and maintenance skills. Those behaviorists working with neurotic clients quickly learned that many of their clients required assertiveness training.

The third trend involved the use of microcounseling procedures to train counselors and psychotherapists in interviewing skills. To those using this method of training and to those trained by it, it quickly became obvious that similar methods could be used to train clients in interpersonal communication skills. Thus, the microcounseling technology has been used to train institutionalized psychiatric clients, parents, marital partners, and families in communication skills.

Communication skills training usually is focused upon two broad sets of interpersonal skills: skills for interacting with one or more persons, and skills involving interpersonal or shared problem solving. Conversational skill training is directed toward the enhancement of an individual's ability to initiate and maintain conversations with other people. This form of training has been employed with institutionalized and formerly institutionalized persons and with individuals experiencing social anxiety. Communication skills training is a central component of most assertiveness-training procedures, since effective communication is seen as an important precursor to assertive behavior.

Another specific form of communication skills training is job interview training directed toward chronically unemployed persons and students about to enter, and others reentering, the job market. Most premarital, marital, and parenting programs, whether developed for therapeutic or preventive/educative purposes, include communication skills training in both interactional and shared problem-solving skills. Many organizational development programs, directed toward increasing the quality of working life, include communication skills training as a critical component. Programs concerned with facilitating interpersonal communication or shared problem solving have been developed for managers, supervisors, and coworkers. With the increasing realization that primary prevention programs are best directed at the younger members of our society, social skills training programs have been developed for use from prekindergarten to high school. Kelly, in *Social-Skills Training,* has presented an excellent review of many of these varied communication skills training programs.

As the various communication skills training programs developed, it became increasingly obvious that there is perhaps a common set of communication skills that pervade the many and varied interpersonal activities in which people engage. Thus, the same communication skills are important in interactions with a person's spouse, children, family, friends, and coworkers. There is a need to identify

these skills more precisely and then to develop a modular program, elements of which can be used to train individuals who are deficient in one or more skills. This approach assumes that assessment methods exist to assess an individual's skill level in each area of expertise.

With the shift from the assumptions of the medical model of intervention to the assumptions of an education or training model has come greater reliance on the principles of instructional psychology. Most communication skills training programs are based on a very similar model of training that involves an instructional sequence, a practice sequence, and a generalization sequence. Gagne and Briggs, in *Principles of Instructional Design,* summarize many of the important characteristics of instruction included in various communication skills training programs.

Initial research in this area involved the demonstration that communication skills training methods produced significant increments in performance during training. A current focus of research involves the demonstration that increments in communication skills performance lead to changes in other behaviors, such as decreased delinquency, reduced drug and alcohol abuse, improved marital and parent-child relations, and improved academic performance. A subsequent concern of researchers is the demonstration that educationally based methods of communication skills training are superior to methods based upon other assumptions, such as sensitivity training. Yet another focus of research has been the specification of the skills that should be included in communication skills training programs and the best methods of training the constituent skills. It can be concluded that communication skills training programs are effective; however, research is still required to develop programs that enhance the generalization of the skills to different situations and over time.

COMMUNITY PSYCHOLOGY: PREVENTION AND INTERVENTION

Community psychology is the study of the interaction between the individual and the environment (Dalton, Elias, & Wandersman, 2001). Community psychologists are interested in examining and improving the quality of life of individuals, communities, and society through collaborative research and action (Jason & Glenwick, 2002). Duffy and Wong (2000) characterized this field as emphasizing prevention over treatment; underscoring strengths and competencies over weaknesses; adopting an ecological perspective that examines the relationships among people and their environment; valuing and respecting diversity and differences; stressing empowerment, which involves enhancing the processes by which people gain control over their lives; emphasizing action research and social change, which provide more alternatives; stressing collaboration with other disciplines; examining how social support can act as a buffer against stress; and focusing on interventions that build a sense of community.

The field grew out of concern for the social and community problems confronting the United States during the 1960s and 1970s (Duffy & Wong, 2000; Tolan, Keys, Chertok, & Jason, 1990). It was formally founded in 1965 at a conference in Swampscott, Massachusetts (Levine & Perkins, 1997), where psychologists stressed the need to emphasize prevention and the importance of targeting the social environment. A core belief of this approach was that the flow of human casualties could be reduced by modifying social systems to make them more responsive and health-inducing or by teaching persons how to live behaviorally healthy lifestyles (Cowen, 1973). Thus, through community-based prevention and promotion, it was hoped that cost-effective services could be implemented, with fewer resources ultimately devoted to remediating hard-to-cure, entrenched problems.

From a more theoretical perspective, several models of prevention have been advanced, the principal ones being social competence, empowerment, and an ecological approach. Some theorists focus on a social competence model, where the goal is to prevent disorders by enhancing individuals' competencies (Duffy & Wong, 2000). Favored by many behaviorally oriented psychologists because of its emphasis on explicit skills, the social competence approach can assist persons in gaining more resources and increasing their competence and independence (Bogat & Jason, 2000; Glenwick & Jason, 1980).

Another approach is the empowerment model, which attempts to enhance people's sense of control over their own destinies (Rappaport, 1981). Empowerment is action-oriented and goes beyond the individual level as emphasized in the social competence model. Individuals, organizations, and communities can be empowered, and in the process they gain greater access to, and power and influence over, decisions and resources (Zimmerman, 2000). One difficulty for practitioners of the empowerment model involves deciding which groups to empower. In many communities, there are opposing groups, with each regarding its perspective as correct.

Another paradigm that has captured the attention of many prevention practitioners and community psycholo-

gists is the ecological model (Kelly, 1985, 1990), which was adapted from the biological field of ecology. Kelly's theory includes four ecological principles that describe characteristics of settings and systems. For example, various components of a system are interdependent, in that change in one part influences change in another. One aspect of the ecological approach for increasing the validity of our understanding of social phenomena is its emphasis on the collaborative relationship between researchers and participants. In such a relationship, concepts and hypotheses are developed and tested jointly by investigators and participants. Individuals should be involved in research projects as participants, not as subjects, with the process of being understood and represented considered to be empowering. Also, including community members in the research and intervention process enables them to receive support, learn to identify resources, and become better problem solvers.

There are many significant problems that our planet is facing, including the need to feed an escalating population, increasing poverty in many countries and excessive waste of resources in others, and environmental degradation. The field of community psychology is committed to finding ways to focus on improving the quality of life through research and action (Jason, 1997). As Albee (1986) argued, in the absence of social change, psychopathology will continue to exist as long as there is excessive concentration of economic power, nationalism, and institutions that perpetuate powerlessness, poverty, sexism, racism, ageism, and other forms of oppression.

COMPARATIVE NEUROPSYCHOLOGY

Results of nonhuman animal research can provide new information that human experimentation does not permit, usually for ethical considerations or because of limited control over complex environmental and genetic influences. The new knowledge can then be used to help understand human disorders. One approach to understanding interspecies brain functions, comparative neuropsychology, involves the direct evaluation of human clinical populations by employing experimental paradigms originally developed for nonhuman animals (Oscar-Berman & Bardenhagen, 1998). Over many decades of animal research, the paradigms were perfected to study the effects of well-defined brain lesions on specific behaviors, and later the tasks were modified for human use. Generally the modifications involve changing the reward from food to money, but standard administration of the tasks in humans still involves minimal instructions, thus necessitating a degree of procedural learning in human and nonhuman animals alike. Currently, comparative neuropsychological paradigms are often used with neurological patients to link specific deficits with localized areas of neuropathology (Fuster, 1997; Oscar-Berman & Bardenhagen, 1998).

The comparative neuropsychological approach employs simple tasks that can be mastered without relying upon language skills. Precisely because these simple paradigms do not require linguistic strategies for solution, they are especially useful for working with patients whose language skills are compromised or whose cognitive skills may be minimal. Comparative neuropsychology contrasts with the traditional approach of using tasks that rely upon linguistic skills and that were designed to study human cognition

(Lezak, 1995). Because important ambiguities about its heuristic value had not been addressed empirically, only recently has comparative neuropsychology become popular for implementation with brain-damaged patients (e.g., see reviews by Oscar-Berman & Bardenhagen, 1998; Squire, 1992). Within the past decade, it has had prevalent use as a framework for comparing and contrasting the performances of disparate neurobehavioral populations on similar tasks.

Although many paradigms have been employed, two popular tasks are classical delayed-reaction tests such as delayed response (DR) and delayed alternation (DA). Both tasks measure a subject's ability to bridge a time gap (see Fuster, 1997). This ability has been termed *working memory,* which is a transient form of memory. Working memory is multimodal in nature, and it serves to keep newly incoming information available online; it acts much like a mental clipboard for use in problem solving, planning, and the like. In the classical DR task, the experimenter places a small reward into a reinforcement well under one of two identical stimuli. The subject is able to see the experimenter put a reward there but cannot reach it. After the experimenter covers the reinforcement wells with the stimuli, he or she lowers a screen, obscuring the stimulus tray. After a delay period, usually between 0 and 60 seconds, the experimenter raises the screen to allow the subject to make a choice. The subject then pushes one of the stimuli away and, with a correct choice, takes the reward; attentional and spatial memory skills are needed to do this. Some investigators have used automated versions of the tasks in which the cues presented to the subjects are lights or sounds, and the subjects are required to respond, after a delay period, by pressing a key or a lever (Oscar-Berman & Bardenhagen, 1998).

DA shares important features with DR. Both are spatial tasks, and both have a delay between stimulus presentation and the opportunity to make a response. In DA, however, subjects must learn to alternate responding from left to right. On each trial, the side not previously chosen is rewarded, and a brief delay (usually 5 seconds) is interposed between trials. Instead of having to notice and remember the location of a reward placed there by the experimenter (in DR), in DA, subjects must remember the side last chosen and whether or not a reward had been available. Subjects must also learn to inhibit, on each trial, the previously rewarded response (i.e., they must not perseverate with consecutive responses to one side only). Rankings of the performance levels of a wide range of mammals, including children, on delayed-reaction tasks have been reported to parallel the phylogenetic scale.

Comparative neuropsychological tasks such as DR and DA are simple to administer and do not rely on intact language abilities. Both tasks also are sensitive to abnormalities after damage to frontal brain systems. Furthermore, successful performance on DR and DA tasks is known to rely upon different underlying neuroanatomical and neuropsychological mechanisms. Thus, the prefrontal cortex is host to at least two subsystems: dorsolateral and orbitofrontal (on the ventral surface). While the dorsolateral system contains intimate connections with other neocortical sites, its connections with limbic sites are less striking than the orbitofrontal system's. The dorsolateral system, although important for successful performance on both DR and DA, is especially important for DR performance, in which visuospatial, mnemonic, and attentional functions are considered critical. By contrast, functions involved in response inhibition have been linked more to the orbitofrontal system. With an inability to inhibit unintended responses comes abnormal perseverative responding, a salient characteristic of orbitofrontal damage. The orbitofrontal system is intimately connected with basal forebrain and limbic structures; its connections with other neocortical regions are not as extensive as the dorsolateral system's. The orbitofrontal system, like the dorsolateral system, supports successful performance on both DA and DR, but it is especially important for DA performance.

Comparative neuropsychological research has provided a framework that is helpful for understanding memory dysfunction in neurodegenerative disorders. In some neurodegenerative diseases (e.g., Parkinson's disease and progressive supranuclear palsy), patients may have working-memory and attentional impairments resulting from prefrontal system damage. In other disorders (e.g., Korsakoff's syndrome and herpes encephalopathy), there are new-learning impairments suggestive of limbic system damage (Oscar-Berman & Bardenhagen, 1998).

Implicit in nonhuman research models of human brain functioning is the assumption of homologous structural-functional relationships among the species (e.g., Milner, 1998; Wasserman, 1993). Research on brain mechanisms that underlie behaviors across species contributes to the discovery of common and divergent principles of brain-behavior relationships.

COMPARATIVE PSYCHOLOGY

Animal behavior is the subject matter of comparative psychology. The first goal of comparative psychology is to identify principles and theories that govern animal behavior. The second goal is to understand how an animal's behavior contributes to its total evolutionary fitness. Historically, comparative psychology has focused on generalizations across species, and ethology has focused on detailed descriptions of particular species.

History

Behaviors and antics of animals have evoked curiosity and amusement in people since antiquity. Pre-nineteenth-century literature and natural history are punctuated with stories, anecdotes, and nonscientific speculations about animal behavior.

The strict separation of animal and human behavior ended with Charles Darwin's theory of evolution, which was the starting point for present-day comparative psychology. Evolutionary development had two important implications: first, that elements of human mentality would occur in animals; and second, that elements of animal mentality would occur in humans. Darwin, well aware of these implications, addressed the first in *The Descent of Man* (1871) and the second in *The Expression of Emotions in Man and Animals* (1872).

Phylogenetic Trees and Phylogenetic Scales

Darwin recognized that the evolutionary process was one of constant diversification. Therefore, evolution can be likened to an enormously elaborated branching tree, with living species represented by the tips of the branches, while the remainder of the tree represents extinct species. In no sense has evolution been an orderly process that produces organisms of increasing subtlety and complexity, culminating in humans. Comparative psychology, therefore, has the virtue of illuminating human behavior as only a small part of a wider context involving enormous interspecies variation.

Similarities in behavioral characteristics of two species with a common ancestor may arise in two different ways. The characteristics may have been present in the common ancestor and survived down to the current descendents, in which case the similarities are homogenous. Alternatively, the characteristics may have been absent in the common ancestor but evolved independently in lines leading to the current species, in which case the behaviors are analogous. Indirect techniques are usually required to infer phylogenetic development of a behavioral trait. For example, if several species sharing a common ancestor all display a behavioral trait, then the shared trait was probably present in the common ancestor (Alcock, 2001). Evolutionary considerations can also lead to questions about how a behavior affected a species's adaptation to its environment and about the role of the behavior in the evolutionary history of the species. Alcock (2001) describes techniques for empirically testing hypotheses about the evolutionary adaptiveness of particular behaviors.

The How and Why of Animal Behavior

There are two fundamental types of explanations for animal behavior. Ultimate explanations are based on evidence suggesting reasons why the behaviors contributed to the fitness of individuals over the evolutionary history of the species. Therefore, ultimate explanations are closely related to the effects of the behaviors in solving a species's problems in its natural habitat.

Proximate explanations address the questions of how a behavior occurs. These explanations answer questions about a behavior's ontogenetic development and how it was affected by learning, physiological and neurological variables, genes, and environmental stimulation. Proximate explanations incorporate variables that exert effects within an animal's lifetime. In contrast, ultimate explanations incorporate mechanisms that have been affecting natural selection long into the phylogenetic past of the species (Alcock, 2001).

Both ultimate and proximate explanations are legitimate scientific approaches to understanding animal behavior. There has been considerable recent interest in finding ultimate or evolutionary explanations for basic learning phenomena that had previously been explained only in terms of proximate causes (Shettleworth, 1998).

Minds and Language

The possibilities and manifestations of mind and consciousness in animals were topics of active speculation in the early post-Darwinian period of comparative psychology. *The Animal Mind* by Margaret Flow Washburn, published in four editions from 1908 to 1936, was a popular and widely used textbook in comparative psychology. But the increasing influence of behaviorism and the warnings of Morgan's canon relegated mind, consciousness, and

similar attributes to the dustbin of comparative psychology.

In 1966 Gardner and Gardner (1971) began tutoring a young chimpanzee, Washoe, in American Sign Language. The project was far more successful than earlier attempts to teach chimpanzees a spoken language.

In the more than 35 years since the original Washoe study, several other ape language projects have been reported, some with manual signing, others in which the ape directed manual responses toward abstract symbols (Rumbaugh & Savage-Rumbaugh, 1994).

In 1993, Savage-Rumbaugh described a remarkable experiment with the bonobo Kanzi showing that he could respond appropriately to a large number of spoken English sentences that he had not previously heard. Kanzi's ability to understand novel spoken sentences is the most impressive evidence to date that apes' language capabilities can closely approximate those of humans who are first acquiring language.

A second important issue in recent comparative psychology is whether apes and possibly monkeys have a theory of mind. Having a theory of mind implies an ability to understand the intentions, mental states, personalities, and perceptions of other animals (Whiten & Byrne, 1997). Tactical deception based on deliberately or knowingly presenting incorrect, deceptive information to another animal is one example of using a theory of mind. Whiten and Byrne (1997) presented evidence of tactical deception in nonhuman primates.

COMPETENCY TO STAND TRIAL

A defendant can be found incompetent to stand trial, under provisions in criminal law, if he or she is unable to understand or participate adequately in his or her defense. If the defendant is found incompetent, further judicial proceedings are suspended until his or her competency is restored. The purpose behind this procedure is to ensure that a defendant receives a fair trial and, in addition, to preserve the dignity of the adversarial process (Melton, Petrila, Poythress, & Slogobin, 1997). The competency standard that is currently recognized by the courts was established in *Dusky v. United States* (362 U.S. 402, 1960), which holds that defendants must be able to consult with an attorney and have a rational and factual understanding of the proceedings.

Competency and criminal responsibility are often confused. However, while competency is concerned with a defendant's present ability to participate in the defense, criminal responsibility refers to a defendant's mental state at the time of the alleged crime. It is quite possible that a defendant could be found to be competent to stand trial and then later successfully raise the insanity defense. Indeed, if the competency issue were to be raised, a defendant would have to be considered competent before being allowed to proceed with an insanity defense.

Based on a thorough review of case law, Bonnie (1992) outlines two types of competence, *competency to assist counsel* and *decisional competency.* Competency to assist counsel refers to the minimum capacities a defendant would need to assist in his or her defense, such as the capacity to understand the criminal charges and the role of defense counsel. These capacities are different from those capacities that may be needed to make decisions that arise in a particular case. Decisional competency refers to the ability to understand and choose among alternative courses of action. In Bonnie's view, it is possible that some defendants could be considered competent to assist their attorney but incompetent to make certain decisions that arise during the course of the defense, such as whether to enter a guilty plea, to waive constitutional rights, or to employ an insanity defense.

Both defense and prosecution can raise the issue of competence. The courts have historically used mental health professionals, including psychologists and psychiatrists, to evaluate competency. Since competency is a legal issue, a judge makes the final determination, but evaluators have considerable influence (Roesch & Golding, 1980). Only a small proportion of defendants referred for fitness evaluations is found incompetent, usually about 10–25%.

Competency evaluations may be intentionally misused by attorneys to delay the trial, investigate the feasibility of an insanity plea, or discover new information about the defendant (Roesch & Golding, 1980). Competency evaluations may also be used as a "back door" to the hospital when a

mentally ill individual does not meet the dangerousness criteria for civil commitment.

Robey's (1965) competency checklist is considered to be the first formalized measure of competency. Following this, the National Institute of Mental Health funded a research project that enabled the development of both the Competency Screening Test (Laboratory of Community Psychiatry, 1973), a 22-item screening test, and the Competency Assessment Instrument (Laboratory of Community Psychiatry, 1973), a more thorough semistructured interview. Other structured and semistructured interviews include the Georgia Court Competency Test-R (Johnson & Mullett, 1987), the Interdisciplinary Fitness Interview (Golding, Roesch, & Schreiber, 1984), the Fitness Interview Test (Roesch, Zapf, Eaves, & Webster, 1998), and the MacArthur Competency Assessment Tool—Criminal Adjudication (Poythress, Bonnie, Monahan, Otto, & Hoge, 2002). Psychosis and, to a lesser extent, mental retardation are the basis for an incompetency determination.

Treatment of competency is, in general, successful. Nicholson and McNulty (1992) found that competency could not be restored for only 10% of defendants. In such cases alternative dispositions, including dismissal of charges or civil commitment, are considered. The most common form of treatment is psychotropic medication (Roesch, Hart, & Zapf, 1996). However, while psychotropic medication may affect a defendant's mental disorder, it does not address his or her psycholegal impairments (Siegel & Elwork, 1992). In contrast, psycholegal education programs do address psycholegal impairments, focusing on topics such as the roles of key players and courtroom procedures (e.g., Pendleton, 1980).

COMPLEXES

The concept of the complex has been used by a number of theorists associated with the psychoanalytic movement. It was introduced by Carl Jung, who is largely responsible for the development of the concept. Jung borrowed the term and the original formulation of the concept from Theodor Ziehen. In studying word association, Ziehen had observed that an individual's reaction time was often long when a stimulus word relating to something unpleasant was presented. He reasoned that such a stimulus was associated with a feeling-toned complex of representations.

In 1900 Jung went to work at the Burghölzli Hospital, where his chief, Eugen Bleuler, introduced the word association test and asked Jung to do research with it. Jung soon came to see his task as the detection and study of complexes. He believed that complexes could be inferred not only from long reaction times but also from physiological reactions, such as the galvanic skin response and changes in respiratory pattern, to certain stimulus words. Jung regarded the complex as a constellation of associated ideas, affects, and images. The constellation can often be viewed as centering on an image corresponding to the idea or situation at the core of the complex—in some cases, an image

of a traumatic event that created the complex. The central idea or image tends in some way to be incompatible with the habitual attitude of consciousness. Since we are inclined to repress such contents or avoid awareness of them, these contents remain largely unconscious. At the same time, they possess a certain wholeness and inner coherence. Because the complex is relatively unconscious, and because some of the energy that would otherwise be available to consciousness is bound up in it, it acts as a somewhat autonomous part of the psyche. In a sense, it can act as a separate subpersonality or splinter personality within the psyche, at odds with the conscious personality.

In the word association test, Jung observed the interference of the complex with the performance of a task undertaken in consciousness. He conjectured that the complex could have similar effects on action and physiological processes in other situations. Thus, he viewed the complex as responsible for slips of the tongue, for gaps in our memory, for the forgetting of names, for accidents—in short, for the various phenomena that Sigmund Freud described as evidence for the operation of unconscious motives.

Traumatic events are evidently one source of complexes. The formative experience might consist of either a single painful incident or repeated episodes of criticism, rejection, or embarrassment in childhood. Jung believed complexes might also arise as a result of moral conflict, a clash between instinctual impulses and acquired values. As he developed the concept of the archetype in his later writings, he came to regard the complex as having an archetypal core as well as ingredients stemming from present-lifetime experience.

Jung regarded neurosis as a dissociation of the personality due to complexes and contended that the symptoms of the neurotic can be understood as the expression of complexes. He recognized, however, that complexes are not necessarily pathological and that they may have both harmful and beneficial effects. He believed that every personality, or psyche, contains a number of semi-independent systems that can be considered complexes.

Jung developed the concept of the complex before his involvement in the psychoanalytic movement. After he became familiar with Freud's work, he sought to relate his own ideas about the complexes to Freud's views of the unconscious. In the subsequent work of Freud, the concept was assimilated into a theoretical system that emphasizes sexuality. Alfred Adler also adopted the concept, but his writings emphasize the striving for power and the sense of inferiority that results from a lack of power. The one complex of importance to Adler was the inferiority complex, which he regarded as a characteristic feature of neurosis.

COMPULSIONS

Definition

Compulsions, along with obsessions, are a hallmark feature of Obsessive-Compulsive Disorder (OCD). According to the fourth edition of the *Diagnostic and Statistic Manual of Mental Disorders* (*DSM-IV;* American Psychiatric Association, 1994), compulsions are "repetitive behaviors . . . or mental acts . . . the goal of which is to prevent or reduce anxiety or distress" (p. 418). Although behaviors resembling compulsions occur at a range of frequencies in the normal population, in order to be considered pathological the compulsions must be associated with either intense distress or functional impairment. Impairment from compulsions can be quite severe, with some individuals spending several hours per day performing rituals, feeling unable to stop and attend to their daily responsibilities. Although the label *compulsion* has been applied to a broad range of repetitive behaviors, including excessive drinking, gambling, shopping, and so on, these behaviors are differentiated from true compulsions by the function they serve. This function will be described in detail later.

Types of Compulsions

While many different classifications of compulsive behavior have been proposed, two of the most common compulsions are cleaning and checking. Hodgson and Rachman (1977) reported that 52% of OCD patients reported checking compulsions and 48% reported cleaning compulsions. Although cleaning and checking appear to be the most common forms of compulsion, other forms of compulsive behavior are also reported frequently. These include collecting or hoarding useless objects, ordering and arranging objects, repeating actions, and seeking reassurance from others (Foa et al., 1995).

Early definitions of OCD maintained that obsessions were mental events and compulsions were overt behaviors. Under this definition, some OCD patients without overt rituals were labeled "pure obsessives." However, current theories recognize that compulsions can be either actions or thoughts; nearly 80% of OCD patients describe mental compulsions (Foa & Kozak, 1995). Mental compulsions are differentiated from obsessions according to their function: that is, whether they elicit distress or reduce it (Foa et al., 1995). Whereas obsessions elicit anxiety or distress, compulsions are defined as overt (behavioral) or covert (mental) actions that reduce or prevent distress elicited by obsessions. Examples of mental compulsions include attempting to think "good thoughts"; counting objects or counting up to a certain number; saying certain prayers in a rigid, repetitive manner; and mentally reviewing past actions or conversations to hunt for mistakes or other infractions. Thus, it appears that nearly all OCD patients have some form of compulsion, either overt or covert.

Association Between Obsessions and Compulsions

For most patients with OCD, obsessions are followed by compulsions. Usually, the compulsions are thematically related to the obsessions; however, there is a broad range of logical coherence of this connection. Washing rituals, for example, are usually motivated by fears of contamination or illness. Checking rituals are usually prompted by worries that an action (e.g., turning off the stove) was performed incorrectly and that some catastrophic event (e.g., fire) will occur as a result. Other connections are less logical: for example, turning a light switch off and on several times in order to prevent one's family from dying in a car accident.

Functional Significance of Compulsions

Given their often bizarre appearance, compulsions are often difficult to understand. Why would an individual choose to engage in such behavior, and why does the behavior persist despite marked functional impairment and distress? Compulsions are best understood within the context of the function they serve. Learning theory models of OCD (e.g., Kozak & Foa, 1997) have traditionally been based to some extent on Mowrer's (1960) two-factor theory of fear. Briefly, two-factor theory posits that classically conditioned fear motivates avoidance behavior. When the organism avoids the feared stimulus successfully, anxiety is reduced and the avoidance is therefore negatively reinforced. The avoidance also prevents extinction of fear by limiting exposure to the feared stimulus; therefore, the fear is maintained. OCD theorists have suggested that compulsions are a form of active avoidance, which are cued by obsessive fears. When the individual performs a compulsion, fear is reduced. Thus, compulsions are negatively reinforced, and obsessive fear is increased. Although there is little evidence for the role of classical conditioning in OCD, studies have supported the anxiety-reduction hypothesis of compulsions: Exposure to feared stimuli increased participants' anxiety, whereas performing compulsions led to decreased anxiety (Hodgson & Rachman, 1972). One problem with a two-factor model of compulsions is the fact that some individuals with OCD report that compulsions are associated with increased, rather than decreased, fear. For example, Röper, Rachman, and Hodgson (1973) found that a subsample of compulsive checkers reported higher levels of fear after checking. Cases such as these might be better explained by Herrnstein's (1969) learning theory, which suggests that mildly anxiety-evoking behaviors might be considered avoidant if they serve to prevent the occurrence of strong anxiety. Thus, although checking may elicit anxiety in some patients, refraining from checking is perceived as even more aversive. In summary, the specific function of compulsions may vary, but the general function appears to be one of anxiety reduction and/or prevention. In this manner, compulsive behavior is negatively reinforced, and extinction of fear is blocked.

Attention to the function of compulsion may help with the differential diagnosis of OCD. Many *DSM-IV* impulse control disorders have been classified as part of an "OCD spectrum." These disorders include "compulsive" overeating, gambling, and sex. However, these problems tend to be functionally distinct from compulsions: They are not triggered by obsessions or fears and are not negatively reinforced by fear reduction. On the contrary, disinhibited behaviors are more likely to be triggered by feelings of tension or boredom, and because the behaviors are satisfying, they are positively, rather than negatively, reinforced (e.g., Steketee, 1993). Although Goldsmith, Shapira, Phillips, and McElroy (1998) point out that this distinction does not apply to every patient, until more convincing data are produced, the term *compulsion* is best reserved to indicate a specific functional relationship between behavior and fear.

COMPUTED AXIAL TOMOGRAPHY (CAT SCAN)

Imaging technology has been very useful in the development of the fields of psychiatry and neuroscience. The past two decades have seen an explosion of this technology, so that we now have a window into the brain and other bodily organs. Much of the early work in this area began with computed tomography (CT), which provided important information about the structure of the brain in various neuropsychiatric disorders, including schizophrenia and affective disorders. Although magnetic resonance imaging (MRI) has largely replaced CT for imaging brain structure in psychiatric disorders, many of the fundamental findings in psychiatry (e.g., enlarged ventricular-brain ratios in schizophrenia) are based on CT research.

The past century's advances in the field of imaging sciences that led directly to CT and other modalities have their basis in the discovery and development of X rays for the imaging of the human body. At the turn of the twentieth century, a physician named Roentgen discovered that passing X rays through the human hand with a photographic plate on the other side created a ghostly image on the photographic plate that represented the bones of the hand, which are hidden from the naked eye. Soon, physicians discovered that X rays could provide a wealth of information about the structure of the human body, both in sickness and in health. The principle of X rays is based on the creation of an X-ray beam. The X-ray beam is created when electrons travel from an anode to a cathode. X rays travel through space like light or sound and have their own specific energy.

X rays travel through different parts of the body at different speeds, depending on the type of tissue that is present. Tissue that is denser or has physical properties will slow down, or attenuate, the X-ray beam to a greater extent than will tissue that is less dense. For example, bone is denser than water (which is basically what the cerebrospinal fluid—the fluid that bathes the brain—is made of, and in fact most of the brain has a density that is fairly close to water). X rays will have a harder time traveling through bone than through water. Fewer of the X-ray photons that travel through bone will be able to make it to the other side of the skull and hit the photographic film in the area corresponding to where bone is present, making the part of the film corresponding to the location of bone look different from the area where there is brain and cerebrospinal fluid. This basic principle, of what are essentially variant forms of light waves (or photons), passing through the body, and the degree to which the photons are slowed down or deflected in their path, providing information about the physical properties of the body that can be used to provide a picture or image of our insides that we cannot see with our naked eye, underlies most of the radiological sciences.

An advance over the use of simple X rays came with the development of the computer after World War II. Hounsfield, an engineer working in London, found in 1967 that images of the interior of the body could be produced by passing X rays through the body at multiple angles and measuring the degree to which the tissues of the body attenuated the X rays. With computers, X rays could be passed through the body at multiple angles, and the information could be reconstructed in an image that provided a map of the interior of the body in exquisite detail. This new technique was used to turn the X-ray images into displays of fine slices, or *tomographs,* throughout the human body, hence the term *computed tomography* (CT). This technology provided images of not only normal human anatomy but also of disease, often giving clues of very small tumors in the body that were less than half an inch in size. Another advance that boosted the resolution of CT over earlier X-ray imaging techniques was the use of photomultiplier tubes over regular radiographic film. With photomultiplier tubes, the radiation reaching the other side of the body interacts with other electrons, resulting in a shower of electrons for each radiation that penetrates the body, effectively amplifying the signal as much as 100 times over the old technique. The improvement is in a parameter known as *sensitivity,* or the ability to detect small amounts of radiation. Another factor that is important in imaging is called *resolution,* or the ability to image very small objects or to determine that two objects that are very close together actually represent two distinct objects. Sensitivity and resolution have been steadily improving in all of the imaging modalities over the past 40 years, which has led to increasingly precise maps of the body's structure and the function of the body.

In the 1970s and 1980s, the development of CT added to our understanding of psychiatric disorders. Scientists used CT to study patients with the diagnosis of affective disorders. CT studies showed that patients with affective disorders, including major depression and manic depression, had atrophy of the brain and enlargement of the large fluid-filled cavities of the brain, called *ventricles,* that also indicated atrophy of the brain. Some patients with depression have an increase in the stress hormone cortisol, and stress has been linked to the development of depression. CT showed that treatment with steroids related to cortisol led to atrophy of the brain. CT studies in patients with depression showed atrophy and enlargement of the ventricles similar to that seen in patients treated with steroids. In some

cases, patients with the highest levels of cortisol had the greatest amount of brain atrophy.

An even larger number of studies have been conducted in Schizophrenia. At least 75% of the 50 or more CT studies in patients with Schizophrenia have found widening of the lateral ventricles compared to control groups. Various methods have been used to measure ventricular size, including computer-based and manual tracing methods. Some studies measured the linear width of the ventricles at their widest point, others measured the volume on several slices, and still others measured volume throughout the brain. The most sensitive method for measuring ventricular size has been the assessment of ventricular volume to brain volume ratios (VBR). Although not all patients with Schizophrenia develop enlarged ventricles, and although these differences are not always large enough to visualize with the naked eye, clearly the majority of studies that use quantitative measures have shown that the mean values of precisely measured lateral ventricular volumes differ from those of normal controls. Other findings that have been consistently found on CT in Schizophrenia include enlargement of the third ventricle, widening of the cortical sulci, and cerebellar atrophy. Positive associations have been found between enlarged ventricles and clinical status (poor social adjustment, poor outcomes, negative or defect symptoms) and cognitive status (neuropsychological deficits). No relationship has been found with treatment history or duration of illness. The significance of these findings is unclear, but many authors have posited a neurodevelopmental hypothesis for neuroanatomical abnormalities in schizophrenia. However, enlarged ventricles have been found in new-onset patients, suggesting that this finding has developed before the onset of clinical recognizable symptoms.

The meaning of enlarged ventricular volumes is unclear. Ventricular enlargement could be related to atrophy of a number of structures that surround the ventricles, including the hippocampus, amygdala, thalamus, striatum, and corpus callosum. Atrophy of structures more removed could also cause ventricular enlargement. The correlation of clinical symptoms with ventricular enlargement, however, is consistent with the idea that these are clinically relevant changes in the brains of psychiatric patients.

In summary, ventricular enlargement in affective disorders and Schizophrenia has been an important and well-replicated finding in psychiatry that was based on the use of CT technology. Although other techniques, such as MRI, have received more widespread use for measurement of brain structure, CT remains an important technique for psychiatry and psychology. The recent development of combined positron emission tomography–computed technology (PET-CT) devices may bring CT back into the realm of research and clinical applications in the future.

J. Douglas Bremner
Emory University School of Medicine

COMPUTER-ASSISTED PSYCHOTHERAPY

Computer-assisted psychotherapy can be defined as (1) the application of computer tools as an adjunct to clinician-administered psychotherapy, or (2) the use of a computer to enhance the efficiency, cost-effectiveness, or delivery of psychotherapy. Attempts were made to adapt computers for use in psychotherapy applications as early as the 1960s (O'Dell & Dickson, 1984; Weizenbaum, 1966; Wright & Wright, 1997). The first program ("Eliza") was intended as an exercise in computer programming, not as a serious effort to conduct psychotherapy on a computer. Although "Eliza" was a fascinating demonstration project, it was not able to communicate reliably with humans using natural language (O'Dell & Dickson, 1984). Most subsequent developers have not attempted to program computers to conduct interviews that simulate communication with a human therapist. Instead, the unique attributes of computer technology have been tapped to design programs that use a variety of media (e.g., text, video and audio, interactive voice response, virtual reality) to educate, give feedback to, and involve users in highly interactive learning exercises (Wright & Wright, 1997).

It has been suggested that therapeutic software could lower the cost of treatment by reducing the number or length of sessions with a clinician required for effective treatment (Wright & Wright, 1997). Several controlled investigations have documented this advantage of computer-assisted therapy (Kenwright, Liness, & Marks, 2001; Newman et al., 1997; Wright et al., 2001). Other possible benefits include improved access to psychotherapy; effective provision of psychoeducation; ability to store, analyze, and display data; systematic feedback to the user; and promotion of the self-monitoring, homework, and self-help components of treatment (Locke & Rezza, 1996; Wright & Wright, 1997).

One of the concerns raised about computer-assisted psychotherapy is that patients could experience being referred to a computer as a dehumanizing experience. However, research with therapeutic software has demonstrated that patients usually report high levels of satisfaction with their experiences in using a computer as part of treatment (Colby, 1995; O'Dell & Dickson, 1984; Wright, Wright, Salmon, et al., 2002). Another concern is that a computer program could never be programmed to have the empathy, wisdom, or creativity of the human therapist. Contemporary developers of computer-assisted therapy programs agree with this observation, and thus do not attempt to simulate the traditional therapeutic interview (Wright & Wright, 1997).

Computers, unlike human therapists, do not have inherent values or ethical standards. However, developers convey their theoretical orientation, values, and ethics in writing software for computer programs. Sampson and Pyle (1983) have offered ethical guidelines for computerized psychotherapy programs that include the following: (1) adequate protection of confidentiality; (2) up-to-date and

accurate information; (3) well-functioning hardware and software; and (4) supervision of the treatment process by a clinician. Some developers of therapeutic software have produced professional and self-help editions (Colby & Colby, 1990; Wright, Wright, & Beck, 2002). The professional edition is intended for use in clinician-directed computer-assisted therapy, whereas the self-help edition is designed to be utilized in a manner similar to a self-help book.

Computer programs for psychotherapy have been based most commonly on cognitive and behavioral methods because these forms of treatment use specific interventions, emphasize psychoeducation, and employ self-help as a primary ingredient of therapy (O'Dell & Dickson, 1984). An example of a computer program oriented toward cognitive-behavioral therapy (CBT) is the software developed in the 1980s by Selmi and coworkers (Selmi, Klein, & Greist, 1982). This program relied completely on written text to communicate with users and is no longer produced. However, Selmi and coworkers demonstrated that computerized CBT could be as effective as standard CBT (Selmi, Klein, & Greist, 1990). Other early software not available for clinical use includes two behavior therapy interventions for anxiety disorders based on the book *Living With Fear* (Ghosh, Marks, & Carr, 1984; Carr, Ghosh, & Marks, 1988; Marks, 1978).

Colby and coworkers (Colby, Gould, & Aronson, 1989; Colby, Gould, Aronson, & Colby, 1991) developed software that integrates computerized instruction with group discussions. The Therapeutic Learning Program identifies problematic interpersonal situations and offers coaching for proactive behavior. It has been used extensively for employee assistance programs. Colby also developed "Overcoming Depression," which utilizes written text and a natural language-based dialogue format (Colby, 1995; Colby & Colby, 1990). A study of this software with depressed inpatients found that the dialogue component of the program did not always communicate effectively with patients and that use of the software did not enhance treatment efficacy (Bowers, Stuart, MacFarlane, & Gorman, 1993; Stuart & LaRue, 1996).

The most recent computer programs for psychotherapy have incorporated new technologies geared toward heightening the power of the learning experience and improving ease of use. For example, Wright and coworkers have designed and tested the first multimedia program for computer-assisted CBT (Kenwright et al., 2001; Colby, 1995; Colby & Colby, 1990). Research with this software demonstrated high acceptance ratings by patients, significant increases in learning of cognitive therapy, and equivalent efficacy to standard CBT (Kenwright et al., 2001; Colby, 1995). Video, audio, and other multimedia elements are used to engage the user and stimulate affect. Users participate in a variety of interactive self-help exercises and are assigned homework to encourage use of CBT in real-life situations. A revised, DVD-ROM version of this software ("Good Days Ahead: The Multimedia Program for Cognitive Therapy") is now available (Colby & Colby, 1990).

Rothbaum (Rothbaum, Anderson, Hodges, Price, & Smith, 2002; Rothbaum, Hodges, & Kooper, 1995; Rothbaum et al., 2001) has pioneered virtual reality technology applications for fear of heights, fear of flying, and Post-Traumatic Stress Disorder (PSTD) in Vietnam War veterans. Controlled trials have found evidence for the efficacy of virtual reality based exposure therapy (Rothbaum et al., 1995, 2001, 2002), but the need for specialized equipment has limited the use of these methods. A more conventional computer program, "Fear Fighter," was developed in Great Britain by Marks and coworkers (Kenwright et al., 2001; Shaw, Marks, & Toole, 1999). This software utilizes text, graphics, and audio to help users plan self-exposure to feared situations and to endure anxiety until it diminishes. Preliminary research suggests that it can substantially reduce the amount of clinician time required for effective treatment of anxiety.

Hand-held computers also have been found to be useful for computer-assisted psychotherapy. Newman and coworkers (1997) found that long-term outcome of computer-assisted CBT for Panic Disorder was equal to standard CBT, even though clinician contact time was reduced to four sessions in those that received the computer adjunct. Gruber and associates (2001) demonstrated the efficacy and cost saving potential of a hand-held computer program added to cognitive-behavioral group treatment for social phobia. Computer-controlled, interactive voice response systems are another possible application of computer technology to perform psychotherapy functions (Greist et al., 2002; Marks et al., 1998). These systems use a conventional telephone instead of a computer terminal or a hand-held device to communicate with the user. Interactive voice response programs for Obsessive-Compulsive Disorder ("BT Steps") and depression ("Cope with Life") have been developed and tested by a team of British and American investigators (Greist et al., 2002; Marks et al., 1998; Osgood-Hines et al., 1998).

Currently, computer programs are not used widely in psychotherapy applications. However, technological advances, increased use of computers in society, and changes in the economics of health care delivery may lead to growth in the use of computer-assisted therapy. If preliminary studies demonstrating patient acceptance, efficacy, and cost-efficiency are confirmed in future research, computer-assisted treatment could become a standard therapeutic tool.

COMPUTERIZED PSYCHOLOGICAL AND BEHAVIORAL ASSESSMENT

The technology boom of the late twentieth century and early twenty-first century was not lost on psychologists and behavior therapists. Researchers have been quick to recognize the potential computers offer in the assessment and treatment of individuals with mental health problems. Efforts to computerize the assessment process, or some component of it, have been made by researchers in all the major theoretical orientations. Computer applications take many forms and are not easily categorized. However, in psy-

chological and behavioral assessment, the following types of applications have emerged.

Computer-assistant programs include software that assists clinicians in collecting client data and/or making diagnostic decisions. For example, researchers have designed *computerized behavior observation systems* to facilitate naturalistic and analog observation of individuals. *Expert systems* are computer-assistant programs that include algorithm structures that are designed to simulate diagnostic-decision making. For example, one group of researchers created a smoking cessation expert system that analyzed assessment data, integrated the information, and made individualized recommendations for treatment strategies in a short report. *Case formulation software* helps clinicians organize important variables operating in a client's life and assists the clinician in developing hypotheses about client functioning. Stephen Haynes and his colleagues have developed a computer program that helps clinicians identify target behavior problems, the effects of those problems, and the causal variables that precede the behavior problems.

Researchers have also developed programs that interactively administer interviews. *Direct computer interviews* are software programs that administer traditional paper-and-pencil questionnaires or structured interviews without the clinician present. These programs typically aggregate data and print reports that assist clinicians in making diagnostic and treatment decisions. Clients may complete the interviews at the beginning of treatment or throughout treatment. For example, Albert Farrell and his colleagues have developed a software program that clients complete at each treatment session to help clinicians monitor client behavior problems.

Virtual reality programs are often used to simulate challenging or feared environments for individuals and can be used in both assessment and treatment contexts. For example, researchers have developed virtual reality programs for phobic individuals that simulate experiences with a feared stimulus. Recently, one research team concluded that phobic individuals are readily immersed in virtual environments and report levels of fear and anxiety similar to what one would expect to see in an exposure therapy session. From a treatment perspective, initial results suggest that exposure therapy conducted via virtual reality is at least as effective as in vivo exposure. Virtual reality systems have also been used with disabled children to assess acquisition of motor behaviors.

Self-monitoring computer programs have taken a variety of formats prior to the computer revolution. *Ecological momentary assessment,* or EMA, refers to the collection of self-monitoring or psychophysiological data in the client's natural environment. Researchers often use handheld computers to administer one or more questionnaires to an individual several times per day at scheduled intervals. The questionnaires are typically brief and usually take no more than a few minutes. Researchers then examine the data for relationships between variables of interest (e.g., mood level and activity). One of the most interesting results from EMA studies thus far is the lack of congruence between client ratings of their own behavior in the natural environment and clinician ratings of client behavior in a structured interview. For example, one group of researchers found in individuals diagnosed with Obsessive-Compulsive Disorder that mean clinician ratings of client symptom severity were almost one standard deviation higher than levels reported by clients in their natural environment.

Computer-based test interpretations (CBTIs) are software programs that generate interpretive reports after assimilating data that are collected by a clinician or a computer. For example, a client might complete a paper-and-pencil administration of a psychological test (e.g., the Minnesota Multiphasic Personality Inventory). The clinician then enters the client's responses into the computer program, and the software generates an interpretive report based on a predetermined algorithm. Alternatively, report generation may be included as an additional feature of a direct computer interview. CBTIs can greatly expedite the process of report writing, but critics argue that they are not sensitive to an individual's unique circumstances, use report-writing rules that are of questionable validity, and tend to produce reports that vague and not clinically meaningful. Most researchers have concluded that CBTIs can be valuable adjuncts to, rather than substitutes for, more individualized clinical assessment and judgment.

Issues In Computerized Assessment

Equivalence

For computer programs that are designed to replicate more cumbersome and time-consuming paper-and-pencil measures or structured interviews, an important consideration is the equivalence of results between the computer version and its parent instrument. How one concludes that data are equivalent is a matter still open to debate. For example, failure to find statistically significant differences between groups using traditional hypothesis testing strategies (e.g., *t*-tests) does not mean that data between groups are equivalent. Currently, there is no commonly held standard for assessing degree of equivalence. The equivalency issue is of more than passing interest because some researchers have found that research participants respond differently when interviewed by a computer. For example, some researchers have found that individuals are more likely to report occurrences of embarrassing, sensitive, or illegal behaviors to a computer than to a human interviewer.

Reactions To Computerized Assessment

Critics of computerized psychological and behavioral assessment have sometimes contended that clients will respond negatively to computer interviews and will be alienated from treatment as a result. Generally, researchers

have not found this to be the case. For example, one group of researchers found that neither college students nor Vietnam veterans showed a preference for a computerized or human-administered format for Post-Traumatic Stress Disorder interviews. Other researchers have reported a trend toward clients' *preferring* the computer interview.

Summary and Conclusion

Computerized psychological and behavioral assessment is a field experiencing exponential growth, which is catalyzed by technological advances and promises to deliver tremendous gains in the coming years. The field will prosper as long as the software applications are developed that help clinicians rapidly and accurately assess client functioning.

CONCEPTUAL LEARNING AND DEVELOPMENT

Bruner, Goodnow, and Austin (1956) presented a theory of thinking that stimulated widespread interest in concept learning. The high interest continued into the 1980s but then lessened except as it related to science concepts. Piagetian theory on children's development of the concept of *number* (Piaget 1952) and of *space* (Piaget & Inhelder 1956), reported in books in English, generated worldwide interest in children's conceptual development. His theory remains a predominant theory of child development.

Klausmeier and his associates began programmatic research in 1960 directed toward testing the theories of both Bruner and Piaget. They found concept learning and concept development to be inseparably related. In turn, Klausmeier reported a rudimentary theory of conceptual learning and development in a 1971 journal article and a refined theory in 1992. The main propositions of the refined theory follow.

Concepts are the fundamental agents of intellectual activity, the basic component of a maturing individual's continuously enlarging cognitive structure. A concept consists of a person's organized information about an item or a class of items. Item as used here refers to an object (e.g. cutting tool), event (e.g., birthday), action (e.g., run), quality (e.g., thick), relationship (e.g., taxonomic), or abstract construct (e.g., eternity).

Concepts that have two or more instances are attained at four successively higher levels of understanding. Specific mental operations that emerge with neural maturation and learning and then become more powerful with further maturation and learning make possible the attainment of each successively higher level.

The four consecutive levels are *concrete, identity, classificatory,* and *formal*. Attainment of the prior level is prerequisite for attaining the next level.

A concept has been attained at the concrete level when the learner recognizes an item (e.g., a clock on the wall) as the same one previously encountered in the identical spatial context or other context in which it was initially encountered. The mental operations involved in attaining a concept at the concrete level are selectively attending to an item, discriminating the item as an entity different from its surroundings, representing the item in long-term memory, attending to the item when it is again encountered in the identical context, retrieving the representation, and using it in recognizing the item as the same one encountered earlier.

Attaining a concept at the identity level involves recognizing an item as the same one previously encountered when it is observed from a different spatiotemporal perspective or when it is sensed in a different modality. The new mental operation that enables attaining the identity level is generalizing that the item, although experienced differently, is the same one cognized earlier.

Attaining the classificatory level requires recognizing at least two items (e.g., the clock on the wall and one on the desk) as being equivalent. Generalizing that at least two items are equivalent is the new operation that enables attaining the classificatory level. Concept attainment of the classificatory level continues until the learner can recognize any instance or noninstance of the concept.

Concept attainment of the formal level is inferred when the individual can identify any instance of the concept and any noninstance, give the name of the concept and the names of its defining attributes, state how any instance of the concept differs from any noninstance in terms of defining attributes, and give the experts' definition of the concept. Abstract thinking with words and other symbols facilitates learning the formal level.

Not all concepts can be learned at all four levels. Concepts for which there is only one instance (e.g., the Earth's moon) are learned only at the concrete and identity levels. Abstract concepts that have no observable instances (e.g., soul) are learned only at the formal level.

Focused instruction accelerates the learning of concepts. The learning aspect of conceptual learning and development theory is based on classroom experiments (Klausmeier, Ghatala, & Frayer, 1974; Klausmeier & Sipple, 1980). Major findings follow.

Repeated presentation of an item is necessary for attaining the concrete and identity levels of a concept. Experience with concept examples and nonexamples is essential for learning to classify correctly. The examples and nonexamples are most effective when the examples differ from one another in their nondefining, or variable, attributes; range from easy to difficult; and are presented concurrently. Providing the learner (1) examples and nonexamples that have nearly the same defining attributes, (2) the name of the concept, (3) the names of its defining attributes, and (4) a definition of the concept facilitates attainment of the formal level.

Giving the learner the name of the concept facilitates at-

tainment of all four levels. Providing a definition reduces the number of examples and nonexamples required. Teaching students a strategy accelerates learning markedly, especially at the classificatory and formal levels.

The time required for attaining the four levels of concepts varies greatly. The time is longer for abstract concepts (e.g., noun) than for concrete concepts (e.g., cutting tool) and for slower cognitive developers than rapid developers.

Students vary greatly in the attainment of concepts. To illustrate, 20% of third-grade students had attained the formal level of *noun* while 21% of 12th-grade students had not.

As a concept is attained from the identity to the formal level it can be used more effectively to (1) recognize instances and noninstances of the concept, (2) understand principles of which the concept is a part, (3) understand relationships of the taxonomy of which the concept is a part, and (4) solve problems requiring understanding of the concept.

There are numerous theories of category learning, one being prototype theory, which was formulated by Rosch (1975, 1978). According to this theory, newly encountered objects are identified as members of a category by comparing them with a prototype that is the best or most typical instance of the concept that was learned earlier.

CONDITIONED FOOD AVERSION

A conditioned food aversion is a learned dislike for and rejection of particular flavors that have been associated with illness. The strength of such learning depends on the procedure used to pair the food with the illness in time, the characteristics of the food, and the nature of the illness.

Conditioning Procedure

The procedure used to produce conditioned food aversions resembles classical conditioning. The conditioned stimulus (CS) is usually a novel flavor, and the unconditioned stimulus (US) is often an emetic agent. The unconditioned response (UR) is not well defined and is assumed to be related to the nausea, malaise, or other internal disruptions induced by the US. After one or more pairings with the US, the CS then comes to elicit a conditioned response (CR) that presumably resembles the illness of the UR, and the animal acts as if the CS is aversive and avoids further contact with it. An important control procedure is an unpaired group that receives equivalent experience with both the CS and US but at sufficiently different times that conditioning to the CS does not occur.

Two types of tests commonly used to evaluate the effects of conditioning are the preference test and the taste reactivity test. In the preference test, animals are given access to a choice between the CS and another neutral substance, such as their normal diet or water. After conditioning, intake of the CS is selectively reduced. In the taste reactivity test (Grill & Norgren 1978), the CS is infused directly into the mouth of the subject, and species-typical ingestive or rejection reactions are quantified. After aversion conditioning with emetic agents, subjects increase their rejection reactions and decrease their ingestive reactions.

In sharp contrast to the traditional classical conditioning procedure, the interval from the CS to US in food aversion conditioning can be as long as a few hours and still produce robust conditioning in a single trial (Garcia, Hankins, & Rusiniak, 1974). These features of aversion conditioning help an animal to learn to avoid poisonous foods without multiple experiences with the poison even if the poison does not immediately make the animal sick.

Characteristics of the Food

The phenomenon of conditioned food aversion is also known as *conditioned taste* or *flavor aversion, poison-based avoidance conditioning, bait shyness,* or *aversion therapy* depending on the interests of the investigator. A taste aversion implies that the aversion is limited to a gustatory CS: that is, one that is sensed by the tongue. A flavor aversion implies that both taste and odor cues compose the CS and that both contribute to the conditioning.

Substances having a bitter, sour, or putrid flavor may evoke an unconditioned aversion, but investigators in food

aversion studies typically use flavors that produce positive ingestive responses, such as a dilute solution of saccharin. After administration of an emetic agent such as lithium chloride (LiCl), a decrease in ingestion rapidly emerges in animals that received the CS and US paired closely in time. Any distinctive taste or flavor can be the target of a conditioned aversion, but some types of flavors seem to be particularly prone to the development of aversions. For example, proteins such as eggs, cheese, and meat are more likely to become targets of conditioned food aversions than carbohydrates, and novel foods are more likely to become targets than familiar foods (Bernstein, 1999).

Nature of the Illness

Unconditioned stimuli that are known to induce food aversions usually produce some type of gastric distress, including nausea, vomiting, or malaise. LiCl is commonly used for experimental treatments in rats. Emetic agents used for conditioned aversion therapy in humans with alcohol dependency include apomorphine, emetidine, syrup of ipecac, disulfiram, ethanol, and others (Howard & Jenson, 1990). Nondrug experimental procedures that produce conditioned aversions include rotational dizziness and some abdominal surgical procedures such as a subdiaphragmatic vagotomy or a bile duct ligation (Lane, Starbuck, & Fitts, 1997). Accidental pairings of harmless novel foods with subsequent gastrointestinal illness probably account for many food aversions in humans, as when persons experience nausea as a result of cancer or cancer chemotherapy.

Other types of treatments that may induce avoidance when they are paired with certain foods or tastes include drugs such as amphetamine, cocaine, morphine, and phencyclidine. Curiously, and in great contrast to the emetic drugs, rats will self-administer these drugs under certain experimental circumstances. The avoidance of a food after its pairing with a rewarding drug may be fundamentally different from the avoidance induced by emetic drugs: After conditioning with a rewarding drug, rats still drink less of a CS in preference tests, but they fail to show large increases in rejection reactions in the taste reactivity test (Parker, 1995).

Neurobiology of Conditioned Food Aversions

Certain parts of the brain related to autonomic activity and emesis become active following administration of an emetic US, and an analysis of such brain activity is improving our understanding of what constitutes the US, UR, and CR in food aversion studies (Bernstein, 1999). The nucleus of the solitary tract (NTS) in the hindbrain receives much afferent input from both the abdominal viscera and the gustatory system, and an injection of LiCl, the US, in rats produces a characteristic pattern of neural activation in NTS as measured by expression of the immediate early gene c-Fos. Intraoral infusions of a preferred solution such as saccharin or of a noxious tastant such as quinine do not by themselves induce c-Fos expression in the NTS, but once saccharin has been paired with LiCl, an intraoral infusion of saccharin alone, the CS, thereafter evokes activity in the NTS as if LiCl had been given instead (Swank & Bernstein, 1994). Thus, the CR as measured by c-Fos expression in the brain resembles the UR. This activation of the NTS results from descending information from the forebrain, suggesting a learning interpretation, and does not result simply from conditioned fear or autonomic arousal (Bernstein 1999; Schafe, Fitts, Thiele, LeDoux & Bernstein, in press).

The neural substrates of conditioned food aversions differ considerably depending on the procedures used to elicit them. Lesions in the amygdala abolish aversions conditioned by intraoral infusion of a CS but do not disrupt those conditioned by drinking the CS from a bottle (Schafe, Thiele, & Bernstein, 1998); lesions of the inferior olive disrupt aversions conditioned by a concurrent acquisition procedure but not by a sequential procedure (Mediavilla, Molina, & Puerto, 1999); and lesions of the area postrema eliminate aversions conditioned by emetic agents such as LiCl (Ritter, McGlone & Kelley, 1980) but not those conditioned by amphetamine or apomorphine (Berger, Wise & Stein, 1973; Van der Kooy, Swerdlow, & Koob, 1983). Clearly, conditioned food aversions are not a unitary phenomenon but represent several different neural processes that may reflect different kinds of learning (i.e., classical and instrumental conditioning).

CONDUCT DISORDER

Conduct Disorder is a repetitive and persistent pattern of behavior that violates societal norms or the basic rights of others (American Psychiatric Association [ApA], 1994), covering four symptom areas: (1) aggressive behavior that threatens or causes physical harm to other people or animals (e.g., bullies, threatens, or intimidates others;), (2) nonaggressive conduct that causes property loss or damage (e.g., fire setting), (3) deceitfulness or theft (e.g., breaking into someone's house or car), and (4) serious violation of rules (e.g., truancy). To be diagnosed, at least 3 of 15 possible symptoms must have been displayed during the past 12 months. Childhood-onset Conduct Disorder is differentiated from adolescent-onset when at least one of the behavioral characteristics is evident before age 10.

Although some forms of aggressive behaviors are relatively common in mild forms during early childhood years, such behaviors become clinically significant if the instances are highly intense, high in frequency, or characterized by notably violent elements in later years. Estimated rates of Conduct Disorder are 6 to 16% for boys and 2 to 9% for girls (ApA, 1994), with boys outnumbering girls about three to one (Kazdin, 1998; Lochman & Szczepanski, 1999). Loeber (1990) hypothesized that aggressive behavior in elementary school years is part of a developmental trajectory that can lead to adolescent delinquency and Conduct Disorder. Similarly, the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV;* ApA, 1994) indicates that Oppositional Defiant Disorder can evolve into childhood-onset Conduct Disorder and then into Antisocial Personality Disorder in adults. Longitudinal research has documented that aggressive behavior and rejection by children's peers can be additive risk markers for subsequent maladjusted behavior in the middle school years (Coie, Lochman, Terry, & Hyman, 1992) and for substance use, overt delinquency, and police arrests in later adolescent years (Coie, Terry, Zakriski, & Lochman, 1995; Lochman & Wayland, 1994). Children are more at risk for continued aggressive and antisocial behavior if they display aggressive behavior in multiple settings and if they develop so-called versatile forms of antisocial behavior, including both overt and covert behaviors by early to mid-adolescence (Lochman & Szszepanski, 1999).

The developmental trajectory leading to childhood-onset Conduct Disorder may start very early among inflexible infants with irritable temperaments (Loeber, 1990). These children are at risk for failing to develop positive attachments with caregivers, displaying high rates of hyperactivity and inattention in the preschool years, and becoming involved in increasingly coercive interchanges with parents and significant adults, such as teachers. Moffitt (1993) has suggested that life-course-persistent delinquents ("early starters") are at risk because of combined biological and family factors. In some children, family dysfunction may be sufficient to initiate this sequence of escalating aggressive behavior. Parents of aggressive, conduct problem children often display high rates of harsh, inconsistent discipline, have unclear rules and expectations, and have low rates of positive involvement, adaptive discipline strategies, and problem-solving skills (Lochman & Wells, 1996; Patterson, 1986).

Loeber (1990) hypothesized that children begin to generalize their use of coercive behaviors to other social interactions, leading to increasingly aggressive behavior with peers and adults and to dysfunctional social-cognitive processes, which in turn serve to maintain problem behavior sequences. For example, aggressive children tend to have hostile attributional biases and problem-solving strategies that rely on forceful, direct action rather than verbal, negotiation strategies, and they expect that aggressive solutions will work (Crick & Dodge, 1994). These information-processing difficulties are made worse for aggressive children because of their dominance-oriented social goals, pervasive schema-based expectations for others' behavior, and strong physiological reactivity in response to provocation (Dodge, Lochman, Harnish, Bates, & Pettit, 1997; Lochman & Dodge, 1998; Lochman & Szczepanski, 1999), as well as their poor verbal fluency and abstract reasoning abilities (Kazdin, 1998). Furthermore, children displaying aggressive behavior are often socially rejected by their peer group and can become more withdrawn and isolated. By early to middle adolescence, they are prone to meeting their affiliation needs by gravitating toward deviant peer groups, which can become an additional proximal cause for delinquent behavior (Coie et al., 1995; Patterson, Reid, & Dishion, 1992).

Historically, psychosocial treatment of antisocial, conduct-disordered youths has been perceived to be difficult and not very productive. However, in recent years random-

ized clinical research trials have identified empirically supported treatments for Oppositional Defiant Disorder and Conduct Disorder. Brestan and Eyberg (1998) have identified two parent-training intervention programs with well-established positive effects (Patterson et al., 1992; Webster-Stratton, 1994) and ten other programs as probably efficacious for treating Conduct Disorder. Kazdin (1998; Kazdin & Weisz, 1998) has similarly identified several positive treatment approaches for Conduct Disorder, including Parent Management Training, Functional Family Therapy, Cognitive Problem-Solving Skills Training, and Multisystemic Therapy. Parent Management Training and Functional Family Therapy are directed at dysfunctional parenting processes and have produced significant improvements in parenting practices and reductions in children's aggressive conduct problem behavior (Alexander & Parsons, 1973; Eyberg, Boggs, & Algina, 1995; Peed, Roberts, & Forehand, 1977; Webster-Stratton, 1994; Wiltz & Patterson, 1974). Cognitive-behavioral treatments designed to assist children's anger management, perspective-taking, and problem-solving skills have produced improvements in children's abilities to accurately perceive others' intentions and to generate more competent problem solutions and have led to reductions in problem behaviors (Feindler, Marriott, & Iwata, 1984; Kazdin, Siegel, & Bass, 1992; Lochman, Burch, Curry, & Lampron, 1984). Multisystemic treatment relies on individualized assessments of antisocial youths and the impaired systems around them (e.g., parents, peer groups, school bonding) and uses intense, individualized treatment plans to affect these systems, producing significant reductions in antisocial behavior among seriously delinquent youth (Henggeler, Melton, & Smith, 1992). In recent years, there has been a focus on developing and evaluating effective multicomponent interventions that target both the social-cognitive and parenting skill deficits evident in Conduct-Disordered youths and their families (Kazdin et al., 1992; Webster-Stratton & Hammond, 1997). Intensive, comprehensive prevention programs have also been developed and evaluated with high-risk children starting as early as first grade, and the results indicate that aggressive behavior and Conduct Disorder can be reduced through early intervention (Conduct Problems Prevention Research Group, 1999; Vitaro, Brendgen, Pagani, Tremblay, & McDuff, 1999).

CONDUCTION APHASIA

Definition and Clinical Findings

Conduction aphasia is a specific language deficit that consists of impaired repetition that is disproportionate to any defects in fluency or comprehension. Literal paraphasias—errors in which incorrect syllables are substituted within words for correct ones—are frequent and are exacerbated by attempts at repetition. In contrast to patients with Wernicke's aphasia, these patients are aware of their deficit and have no difficulty in comprehension. Ideomotor apraxias—inability to perform a manual task despite comprehending its goal—can also be present. To neurologists conduction aphasia is an important clinical finding because it reliably indicates a brain lesion involving the dominant posterior perisylvian region. To cognitive neuroscientists, conduction aphasia stands at the center of a long-standing debate on whether complex behaviors are created from joining of simple cortical regions or are mediated by more specialized cortex.

Localization

Classically, conduction aphasia results from lesions of the arcuate fasciculus that disconnect receptive from expressive language regions. The arcuate fasiculus is a white matter tract that runs from Wernicke's area in the posterior superior temporal gyrus, arches around the sylvian fissure, and runs anteriorly to the inferior frontal lobe of Broca's region.

Many lesions that cause conduction aphasia not only involve the arcuate fasciculus but also include the supramarginal gyrus and, sometimes, the posterior superior temporal gyrus, the left auditory complex, and portions of the insula. Most cases of conduction aphasia follow cerebral infarcts of the dominant hemisphere involving thromboembolic occlusion of a posterior branch of the middle cerebral artery. It is relatively rare in comparison to other major aphasias (global, expressive, and receptive) because thromboemboli usually lodge more proximally, causing more anterior or widespread infarcts.

Carl Wernicke postulated that a lesion of the arcuate fasciculus that disconnected receptive from expressive centers would produce a deficit in repetition, or *conduction aphasia.* Others proposed that a single cortical center was responsible for integration of receptive and expressive regions yet was independent of them (Goldstein, 1948). This hypothesis lead to adoption of the alternative term *central aphasia* because the specific cortical region mediated central or inner speech.

Evidence Supporting Disconnection

Evidence from subjects with conduction aphasia usually supports the concept of disconnection. In these studies (usually patients with strokes examined at autopsy or by neuroimaging), disruption of the arcuate fasiculus is obligate with variable involvement of adjacent regions of supra- or subsylvian cortex (Benson et al., 1973; Damasio & Damasio, 1980). Studies of cortical strokes in determinations of cortical versus subcortical mechanisms can be misleading, however, because regions of destruction involve both cortex and the arcuate fasciculus.

Circumscribed lesions of the arcuate fasiculus that spare overlying cortex also support disconnection (Aihara et al., 1995; Arnett, Rao, Hussian, Swanson, & Hammeke, 1996; Tanabe et al., 1987), but with white matter lesions (caused by multiple sclerosis, for example) it is not possible to differentiate between the relative importance of disruption of the arcuate fasiculus and disconnections of overlying neurons along its course.

Physiological findings have also supported disconnection

as the mechanism of conduction aphasia. Regional blood flow determined by xenon CT-scan was absent in Broca's region in stroke patients with conduction aphasia, suggesting functional disconnection (Demeurisse & Capon, 1991).

Electrical stimulation, unlike clinical-pathological correlations in stroke, can more selectively separate cortical from white matter dysfunction. Electrical stimulation of eloquent cortex produced both Broca's and Wernicke's aphasias but not conduction aphasia (Schäffler, Lüders, & Beck, 1996), suggesting that conduction aphasia is not cortically mediated. Notably, in this series of patients with implanted subdural electrodes, the testing paradigm involved mainly reading aloud, and repetition may not have been tested (Schäffler et al., 1996).

Evidence Supporting Cortical Specialization

Other studies suggest that disconnection may not be the only mechanism of conduction aphasia. Some cases of conduction aphasia were caused by lesions that clearly spared the arcuate fasciculus (Marshall, Lazar, Mohr, Van Heertum, & Mast, 1996; Mendez & Benson, 1985). Similarly, lesions confined to the arcuate fasciculus have not always resulted in conduction aphasia (Shuren et al., 1995).

Physiologic data provided by positron emission tomography (PET) imaging does not clearly support the disconnection theory. In one study of stroke and conduction aphasia, cerebral metabolic patterns had no clear correlation to clinical findings (Kempler et al., 1988), suggesting that functional disconnection is not necessary to produce conduction aphasia.

PET studies are correlated by two independent reports of cortical mapping using electrical stimulation of implanted electrodes. In these cases, impaired repetition, with other features of conduction aphasia, was transiently elicited by stimulations of the posterior superior temporal gyrus (Anderson et al., 1999; Quigg & Fountain, 1999). The selective and reversible impairment of a specific region of cortex suggests that conduction aphasia is mediated by regions of specialized cortex.

Although the classic Wernicke model is insufficient to account for all cases of conduction aphasia, it remains a clinically useful means by which to organize deficits in language.

CONFIDENCE INTERVAL

The concept of the confidence interval was introduced and developed theoretically by Neyman in the 1930s. The confidence interval represents the range of values around a parameter estimate that indicates the degree of certainty that the range contains the true value of the population parameter. The upper and lower boundaries of the range are the confidence limits. The width of the confidence interval indicates the degree of precision associated with the parameter estimate. Wider intervals indicate less precision, and narrower intervals indicate greater precision. The width of the interval can never be zero, because there will always be some sampling error associated with estimating a population parameter from sample data. Sampling error may be due to measurement unreliability or other chance factors that cause fluctuations from sample to sample. The result is that no matter how carefully a sample is drawn or how large it is, there can be no certainty that the sample estimate is exactly equal to the parameter (population) value.

The calculation of the confidence interval for any parameter is based on the standard error of the relevant sampling distribution. For a simple observation, X, assuming an underlying normal distribution with mean μ and standard deviation σ, the confidence limits on the observation can be stated simply as $X = \mu \pm z\sigma$, where z represents the standard normal deviate associated with any particular level of confidence. Any confidence level may be specified, but in practice the most commonly used intervals are the 95%, 99%, and 99.9% levels:

95% confidence limits: $-1.96\sigma \leq X - \mu \leq 1.96\sigma$

99% confidence limits: $-2.58\sigma \leq X - \mu \leq + 2.58\sigma$

99.9% confidence limits: $-3.29\sigma \leq X - \mu \leq + 3.29\sigma$

During the early decades of research in experimental psychology, confidence intervals of 50% were commonly reported, based on the concept of the probable error ($\mu \pm 0.6745\sigma$). It is now seldom used and is generally considered obsolete.

Confidence limits can be computed for any sample statistic for which the sampling distribution is known. For example, for the mean (M), the standard error of the mean (σ_m) is used, so that $M = \mu \pm z\sigma_m$. If the population mean and standard error are not known, which is often the case, estimates of the mean and standard error based on observed samples may be substituted. However, in this situation, the confidence limits must be set using the t-distribution rather than the normal (z) distribution. When sampling distributions are unknown or seriously depart from the normal distribution, various advanced techniques can be employed to estimate the standard error from observed data, such as bootstrapping, jackknifing, and computer simulation. Confidence intervals are most commonly reported for well-known statistics such as sample means, correlation and regression coefficients, proportions, and predicted scores, but they should also be determined for less commonly used statistics, such as measures of effect size and goodness-of-fit indexes.

As an example of the use of confidence intervals, consider an incoming class of 750 college freshman with an average recorded Scholastic Aptitude Test (SAT) score of 550. Assuming an underlying normal distribution with $\mu = 500$ and $\sigma = 100$, then $\sigma_m = 3.65$. The resulting 95% confidence interval is 543–557. This interval is typically interpreted as meaning that there is a 95% chance that the interval 543–557 contains the "true" value of the freshman class SAT score. However, since any specifically computed interval either does or does not contain the true score, it is probably fairer to say that if a very large number—in principle, an infinite number—of such group means were sampled, 95% of the resulting confidence intervals would contain the true score.

The use of confidence intervals is increasingly being recommended as a substitute for statistical significance testing. This position received its first major explication by Rozeboom in 1960 and has been elaborated by others since, especially Cohen. This position holds that null hypothesis significance testing is a barrier to progress in behavioral science, especially with respect to the accumulation of knowledge across studies. The use of confidence intervals, in conjunction with other techniques such as meta-analysis, is proposed to replace traditional significance testing. The idea here is that confidence intervals can provide all of the information present in a significance test while yielding important additional information as well.

CONFIDENTIALITY

Confidentiality is fundamental to effective diagnosis and treatment of mental illness. Although privacy and confidentiality are important to many aspects of health care, mental illness is among those disorders that evoke special concerns for privacy on the part of people who suffer from them, because of stigma, shame, feelings of failure, and possible detrimental effects if their mental and emotional conditions were to be known. Loss of employment, public embarrassment, disrupted relationships, and loss of insurability are among the potential consequences that people fear. Even more sensitive are the revelations that patients make in the course of psychotherapy, where complete openness and honesty are vital to the treatment process.

Some definitions are in order. *Confidentiality* characterizes a mutually understood, societally defined relationship between two parties, in which full disclosure and trust that the disclosed information will not be revealed are essential to the recognized function of the relationship. Such relationships may be professional, as in the case of doctor-patient, attorney-client, or clergy-penitent relationships, or they may be personal, as with husband and wife. Because of its characterization as part of a special relationship, confidentiality is distinct from *privacy,* which is a broader right not to have one's personal life, person, property, financial status, and so on invaded by or exposed to others. It is also distinct from *privilege,* which refers to legal protection of specified information from disclosure in certain judicial proceedings or governmental hearings. To relate these three concepts, one may view confidentiality as a particular, relationship-specific form of privacy, which may be protected by the laws of privilege in legal proceedings.

Confidentiality in medical settings has long been recognized as a key element of medical ethics. The Hippocratic Oath of ancient Greece is the foundation of modern ethical codes for not only medicine but also other healing profes-

sions. One translation of this code is that "Whatsoever I see and hear concerning the life of men, in my attendance of the sick or even apart therefrom, which ought not to be noised abroad, I will keep silence thereon, counting such things as holy secrets." A related principle of the medical profession is *primum non nocere:* First and foremost, do no harm. A breach of confidentiality can do great harm and expose the offending professional to significant liability. The highly trained professionals who treat mental illness—psychiatric physicians, psychologists, social workers, mental health counselors, nurses—are bound by the ethical standard of guarding confidentiality. Even the fact that a patient or client is receiving treatment for mental illness is subject to this constraint.

The disclosures of a patient in psychotherapy are especially sensitive. Although various methods of psychotherapy require differing degrees of personal disclosure, patients generally expect to speak freely about the private details of their mental and emotional life. This is especially true of psychotherapy based on psychoanalytic principles and methods. The laws of all states protect the confidentiality of disclosures in psychotherapy. The U.S. Supreme Court strongly affirmed the special protection of the contents of psychotherapy in its historic 1996 decision in *Jaffee v. Redmond,* in which the court declined to permit access to information from the psychotherapy of a policewoman who was sued for killing a suspect in the line of duty. The court's rationale recognized psychotherapy as a personal and social good that could not take place without confidentiality. The decision declared that "Effective psychotherapy . . . depends upon an atmosphere of confidence and trust in which the patient is willing to make a frank and complete disclosure of facts, emotions, memories, and fears. Because of the sensitive nature of the problems for which individuals consult psychotherapists, disclosure of confidential communications made during counseling sessions may cause embarrassment or disgrace. For this reason, the mere possibility of disclosure may impede development of the confidential relationship necessary for successful treatment." The court established an absolute privilege protecting confidentiality in court proceedings—absolute in the sense that a judge is not free in an individual trial to balance the adverse effects of disclosing confidential material from psychotherapy against other considerations such as the possible value of such a disclosure in seeking the truth in the trial.

The Privacy Rule promulgated in 2000 by the U.S. Department of Health and Human Services as mandated by the Health Insurance Portability and Accountability Act (HIPAA) of 1996, which took effect in April 2003, established additional governmental protection of personal disclosures in psychotherapy. Mental health professionals may document the contents of psychotherapy sessions in "psychotherapy notes," a part of the medical record kept separate from the rest of the record. Only with the patient's specific authorization may a therapist disclose the contents of those notes. Authorized disclosure may not be coerced as a condition of rendering or paying for the treatment, as by an insurance company or a managed care organization. Limited exceptions include disclosure to "avert a serious and imminent threat to health and safety," for a medical examiner determining the cause of a patient's death, for defense of the therapist if sued by the patient, or for oversight of the professional by governmental bodies. The privacy rule outlines basic elements to be documented in the general medical record in contrast to what would usually appear in the protected psychotherapy notes at the therapist's discretion.

Much controversy took place in the development of the HIPAA privacy rule, particularly about a provision that the patient's written consent would be prerequisite for all disclosures for purposes of "treatment, payment, and health care operations." This applied to all medical situations, including mental health care. Over the strong objections of privacy advocates, who contended that having no choice regarding consent for disclosures would deter patients from seeking care, the government removed that requirement in 2002. In so doing, the government yielded to those who contended that strict application of the rule would severely interfere with communications essential for emergency care or the efficient delivery and management of services. Patients must instead be informed of their privacy rights and protections. Individual practitioners remain free to request the patient's consent, although under the regulation they are not necessarily bound by the patient's decision. The change did not alter the protection of psychotherapy notes. More stringent protections imposed by individual states would take precedence. The privacy rule also mandates that disclosure must be limited to the minimum amount of information necessary to the purpose of the disclosure. The privacy rule applies only to entities that communicate medical information by electronic means. Many details of the implementation of HIPAA regulations for security and electronic communications remain to be worked out.

CONSTANCY

We perceive objects and events by their effects on our sense organs—the light they provide the eye, the pressure waves that enter the ear, and so on. An object's physical attributes, such as its size, shape, and reflectance, are *distal* stimuli: properties that are relatively invariant for a given object, and important to our dealings with the world. To perceive these properties, we must extract information about them from the patterns of stimulus energies at our sense organs—the *proximal* stimulation, which changes constantly. Thus, varying the viewing distance, viewing angle, and il-

lumination changes the size, shape, and brightness of the object's proximal stimulus. Nevertheless, things do not generally seem to expand when approached or become less reflective when moved from light to shade. These phenomena are given appropriate names: *size constancy, lightness constancy, position constancy,* and so forth.

This general rule, as formulated by Hermann von Helmholtz, can be paraphrased as follows: One perceives that state of affairs in the world that would, under normal conditions, have given rise to the pattern of proximal stimulation that one's sense organs receive.

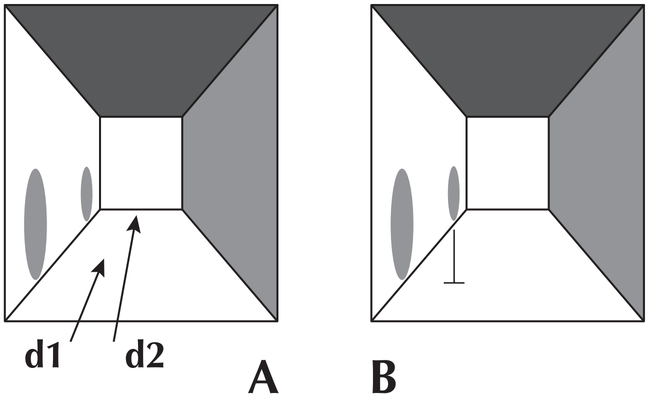

Figure 1. Size constancy and attention: (a) If seen in perspective against the left wall, at the different distances d1 and d2, the two ovals look like disks of equal sizes against the left wall. (b) If you can see them as at the same distance, by attending to the stand under the right-hand one, they appear of very different size.

Theories and Implications of Constancy

There have been several general approaches, differing in purpose and scope, to explaining how the perception of unchanging distal attributes is achieved, given the changing proximal stimulation.

Classical Theory of Constancy

The first explanation, central to the Helmholtzian classical theory of perception, is that we apply (usually unconsciously) what we have learned from our experiences with physical regularities of the world, and we thereby infer (also unconsciously) what the distal situation around us must be. Thus, we use the information about the distances (**d1, d2**) implied by the *perspective* in Figure 1A to estimate the gray disks' distal sizes, given their proximal sizes as picked up by the receptors in the retina. Similarly, we take the differences in illumination and our knowledge about how light bounces off surfaces to estimate the reflectance in each case of color or lightness constancy.

Note that this theory of the constancies assumes the viewer has considerable mental structure available beyond the information in the proximal stimulation and has learned the ecological likelihoods involved. It does explain many other perceptual phenomena as well, including contrast and other illusions, and many of the Gestalt phenomena of organization.

Direct Theories of Constancy

We now know that the classical explanation of the constancies is not the whole story, because animals with no prior visual experience nevertheless display adequate perceptual competence. The perceptual approaches known as Gestalt theory and direct theory, both strongly opposed to the classical view, hold that so long as the distal stimulus is invariant, some aspects of proximal stimulation will be invariant, in spite of changing size and luminance in the retinal image. This argument had been offered earlier by Ewald Hering and Ernst Mach, and it has since formed the core of two quite different direct theories of constancy.

The first of these are what can be termed *physiological theories of constancy.* Hering and Mach had proposed that innate networks of lateral connections exist between the receptors, as well as in the higher levels of the nervous system, and these might contribute to some of the perceptual constancies (particularly color constancy).

Such interconnections have now been demonstrated and measured, and they must surely affect how we perceive. Put simply, a more strongly illuminated region in the retinal image reduces the response of adjacent regions of the retina through a process of *lateral inhibition.* When the illumination falling both on an object and on its surroundings increases, there is an increase in both the light reflected to the eye from the object and the light from its surround, so the inhibition from the latter reduces the neural response to the former. The response to the light from the object therefore normally remains relatively unchanged, despite changes in the illumination, so long as the objects' and surroundings' reflectances remain constant. (Several common illusions are covered by the same explanation, notably examples of *contrast,* as when a bright surround makes a gray object look darker.) L. Hurvich and D. Jameson developed and tested a quantitative model of chromatic color constancy for simple patterns, thereby testing as well their model of red/green, yellow/blue, white/black opponent pairs, which itself was based originally on Hering's theory of color receptors.

Of course, there are reasons aside from testing underlying theories to study the constancies, like the needs of imaging technologies. For example, mathematical algorithms in the fields of color science and computer vision, notably by B. Wandell and colleagues, have recently been aimed at separately estimating surface colors and their illumination, using pictures of natural scenes. More generally, the attempt to explain *constancies as direct responses to stimulus invariances* avoids both questions of physiological mechanisms and questions of Helmholtzian inference. Thus, when the illumination changes, both the light reaching the eye from an object and the light from its surround change, but the *ratio* of their intensities remains invariant. It has

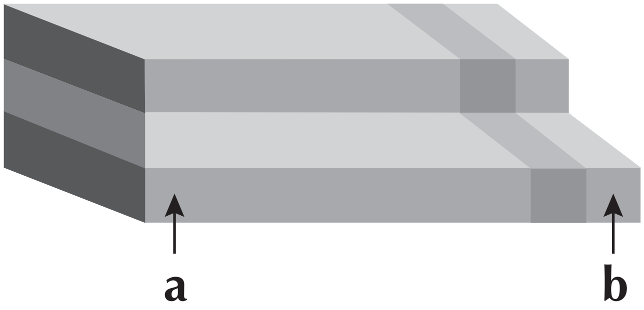

Figure 2. Adelson's impossible staircase.

been recognized since Hering that if sensed lightness were a response only to such a ratio, lightness constancy (and lightness contrast) would then be a direct response to that variable of stimulation.

Most generally, J. J. Gibson argued that for most properties the changing proximal stimulus pattern received by a perceiver moving around in an evolutionarily normal environment offers invariants that reflect the structure of the physical world and therefore make any inferencelike processes wholly unnecessary.

Inference and Attention in Constancy

Although the direct approach is potentially highly useful, there is no evidence that most constancies are direct responses to such invariances. Moreover, many examples of attention-dependent taking-into-account processes remain, needing explanation. In Figure 2, devised by E. Adelson, although **a** and **b** are identical as printed, **a** looks like a dark (paint-striped) surface and **b** looks like a light surface in shadow, depending on where one attends; similar attention-dependent examples can be shown in judging size, shape, and the like. Thus, in Figure 1B, the right disk looks smaller than in 1A, if you attend its dim stand. Attention (and perceptual inference) remain involved.

CONSTRUCTIVISM

In traditional philosophy, the commodity that goes by the name of *knowledge,* whether based on information conveyed by the senses or on insights of intuitive reason, is always expected to represent an external reality in some way analogous to the way pictures represent what they are supposed to depict. The constructivist theory of knowing breaks with this tradition and posits a different relationship between knowledge and the real world. The activity of knowing is seen rather like that of a river that finds its way through the constraints presented by a landscape. The river does not discover what the landscape is like, but by trial and error it finds a way to flow. The path the river takes is determined on the one hand by the constraints of the landscape and on the other by the constraints implicit in the "logic" of water, which prevents the river from flowing uphill. In the constructivist view, then, knowledge does not regard what may or may not exist, but focuses (like the pragmatists' view) on what has proven successful.

Instead of speaking of truth, indicating that a piece of knowledge matches reality, constructivists speak of *functional fit,* by which they mean that their knowledge is expected to fit into the world of their experience. A concept, a way of thinking, or a theory is therefore said to be *viable* if experience shows that it does what is expected of it.

This change of perspective entails two basic principles: (1) Knowledge is not passively received but actively built up by the cognizing subject; and (2) the function of cognition is adaptive and serves the organization of the experiential world, not the discovery of ontological reality.

The Swiss psychologist Jean Piaget, the father of the constructivist school in the 20th century, characterized the situation by saying: "The mind organizes the world by organizing itself." This is often erroneously interpreted as an expression of philosophical idealism. It is a misinterpretation because it disregards the fact that Piaget considered knowledge a form of adaptation, and the world the mind organizes is not what idealist philosophers call reality, but the world of the individual's practical experience. Such a pragmatic position is perfectly compatible with views expressed by the great physicists of the 20th century, who held that physical theories are *models* of the experiential world, not descriptions of an observer-independent reality.

The constructivist theory of cognition, although formulated a decade earlier, has two obvious parallels to conceptions in the discipline of cybernetics. On the one hand, the process of cognition is a prime example of *self-organization* and can be seen as a continuous chain of *feedback loops* in search of viable ways of acting and thinking. On the other hand, the constructivist theory of language and its meanings is in agreement with Shannon's theory of communication, according to which signals (or words) do not carry meaning in themselves but are given it by the sender and the receiver on the basis of their individual experience in social and linguistic interaction.

Relinquishing the view of communication as a form of transportation (meanings being conveyed from sender to receiver) makes it necessary to consider that students' interpretation of texts and teachers' discourse is inevitably

subjective and driven by the natural desire to organize their own experiential world in a reasonable, manageable fashion. This has several important consequences for the practice of education. First, a radical distinction has to be made between educational procedures that aim at generating understanding (teaching) and those that disregard conceptual development and aim at generating the repetition of specific phrases and behaviors (training). Second, the researcher's as well as the educator's interest will be focused on what can be inferred to be going on inside the student's head, rather than on overt responses. Third, the teacher will realize that knowledge cannot be transferred ready-made to students because conceptual structures can be built up only by them. Language, therefore, cannot serve as a means of transmission but only as a tool in the process of orienting each student's construction. Finally, students' "errors" and instances in which their answers deviate from the teacher's expectations will be of particular interest, because these deviations tend to throw light on how the students, at the particular point in their conceptual development, are organizing their experiential world.

During the last 20 years, constructivism has had an acknowledged influence on the teaching of mathematics and science. Instances in which it was put it in practice have been generally successful, and the relevant literature is full of such evidence. But there has also been the inevitable backlash and attempts to mitigate the school's adamant agnosticism with regard to ontological reality. One of these attempts is called *constructionism* and holds that the conceptions of language and society reflect things that have an independent existence beyond the constructions of individual minds. However, the assumption of any such correspondence remains a metaphysical fiction as long as no indication is given as to how its viability could be experientially achieved or confirmed. Constructivism, the school of thought discussed in this entry, is a theory of cognition and concerns, not what might exist, but only what can rationally be known.

CONSUMER RESEARCH

Each one of us is a consumer. We eat, sleep, bathe, dress, exercise, gather, read, travel, and perform a host of other daily and weekly activities. In an earlier era it was a major challenge to find any product or service to meet a given need. If a product or service was available and affordable, it was readily accessed and used. This reality continues to be true in underdeveloped, third world countries; but industrialized nations—those that commonly comprise the world's Group of Eight (G8)—provide a very different picture and challenge. In these countries, every item and service comes in a vast array of brands representing an equally vast array of companies. The challenge is no longer simply to get a specific product or service to market and consumers. Now the challenge becomes one of assuring that the consumer will prefer and will purchase a specific brand of product or service . . . the chosen one among the available many. To meet this challenge, companies invest heavily in research to learn about their prospective consumers, their habits, their personalities, and their preferences. To misread the consumer can spell millions of dollars in company losses and, in some instances, bankruptcy. Because the stakes are high, methodical information-gathering becomes essential and critical.

Definition and Evolution

Consumer research systematically studies the many aspects of human behavior related to the purchase and use of economic goods and services. The product-related focus includes research in advertising effectiveness, product features, and marketing techniques. Focus upon the consumer has included the study of attitudes, feelings, preferences, and the many group influences upon the decision-making process of the individual consumer. The field also studies the consumer as a citizen and a central figure in social/environmental problem solving. This scope and range make consumer research highly interdisciplinary. It integrates theoretical concepts and research approaches from social psychology, sociology, and economics.

Although in one sense consumer research is as old as the dawn of recorded human history, in still another sense it is as young as the last few decades. Not until the 1920s did consumer research begin to focus on two-way communication: gathering information from consumers to prepare more effective advertisements. Still later, attention was given to consumer attitudes and opinions prior to product design. As this consumer focus steadily grew, it marked the appearance of a newly independent member of the advertising family: consumer psychology. Official recognition came in 1960 when the Division of Consumer Psychology was formed within the American Psychological Association.

The early-era, primitive question was one of "What do people need?" Economic growth and increased personal income spawned the more probing questions of "What do people want?" and "What can people be enticed to want?" It is these questions that form the basis of consumer research today.

Consumer research takes many forms and spans many different settings. Prevalent forms include a variety of survey and polling methods, in-depth projective techniques, and behavioral studies.

Research Methods

Survey and Polling Techniques

Most research utilizes some form or variation of survey or polling. It has the advantage of gathering input from large

groups of consumers quickly and relatively inexpensively. This research approach assumes that consumers know their likes, dislikes, and preferences and will be forthright in expressing them.

The method is premised on random selection of consumers within a target market. Where this market is the U.S. population at large, the survey or polling typically focuses on carefully selected communities that, taken collectively, proportionally represent the various constituencies comprising the broader community. Where the market is more product-line-specific, a select group of consumers in a given demographic or socioeconomic group becomes the focus. For example, parents of young children might be surveyed to check cereal or other food preferences.

The survey and polling methods themselves are wide-ranging. Selected consumers may receive a survey by mail, may be visited at home by an interviewer, may be telephoned, or may be computer-accessed by the Internet. Other consumers may be surveyed within a grocery store or a shopping mall. They may be asked about a specific product, sizes, colors, textures, and shapes. They may be asked to come into a mall-based test room where they express actual preferences of products or features. Or, in the case of food items or personal hygiene products, they may be asked to try different samples and register preferences. Logical consumers of a given product (e.g., mothers with infants, where the product is baby-care-related) may be gathered in focus groups to determine product features and preferences.

Rapid technological advances have brought prominent growth in surveying by Internet and the prospect of virtually instant response via integrated systems combining cable, computer, and television. Although the technologies will rapidly change, the basic principles underlying surveying and polling will remain constant—principles of random sampling within representative general or target-market populations.

In notable instances, polling or surveying will target those consumers who have purchased a given product or brand. What attracted them to the product, why they selected it, how satisfied they are with its features and performance, and related questions hold central interest for the company whose product was selected or, in some instances, a competing company who seeks to win the consumer in the future. The questionnaire may come in the just-purchased box of shoes, radio alarm clock, or computer. Purchaser surveying is the only consumer research method used by Japan. It is their belief that random surveying within the broader consumer population is too capricious and subject to change.

Depth/Projective Techniques

Projective techniques probe below the surface of a consumer's cognizant behaviors, preferences, and motivations. These techniques are premised on the belief that consumers in the marketplace are motivated by desires they do not know and cannot express consciously. To access these motivations, the technique, in effect, removes the question from the person through interpretation of abstract stimuli or pictures, sentence or story completion, questions about what their neighbor would consider most important in selecting a given product, descriptions of the personality of a consumer who would select a given product or grouping of products, and so on. Through techniques such as these the consumer unwittingly expresses her or his own underlying motivations while responding on the basis of stimuli, sentences, or other individuals.

Historically, projective techniques have been very meaningful in designing advertising campaigns to effectively move beyond a marketing problem or roadblock. When Duncan Hines introduced a cake mix that required only adding water, it sat quietly on supermarket shelves. Projective techniques revealed the guilt homemakers felt at baking a cake so easily, and the product was reformulated to require adding an egg. Similar projective techniques have been useful in revealing and overcoming resistances in a wide variety of product areas including microwave dinners and instant coffee, to name but a few.

Behavioral Techniques

Behavioral techniques examine the actions of the prospective consumer in several facets of the purchasing arena. Children and their parents may be invited to shop in a mock grocery or toy store. Consumers and their actions in store aisles may be observed firsthand or through one-way-mirrors. Selected consumers may be given scanner cards that register all their purchases at designated scanner-cable-equipped supermarkets. These scanner-cable panels of consumers provide important data to major food manufacturers.

Conclusion

Although this discussion has focused upon the commercial marketplace, the techniques of consumer research are used extensively in broader nonprofit and societal orientations as well. Questions of consumer welfare, product safety, and truth-in-packaging legislation have been central among these broader concerns. Equally central have been issues relating to quality of life and the reciprocal nature of consumer behavior: (1) the responsibility of society toward the individual consumer, and (2) the responsibility of the individual consumer toward society. Society's responsibility encompasses areas such as health care delivery systems, education, and cultural and recreational facilities. The individual consumer's responsibility encompasses respect for the environment, for communities, and for natural resources.

CONTEXTUALISM

Contextualism is a philosophy of science based on modern variants of American pragmatism. The core analytic unit of contextualism or pragmatism is the ongoing act in context: the common sense–situated action. It is doing as it is being done, such as in hunting, shopping, or making love. This has sometimes been termed the *historical act,* but not in the sense of a thing done in the past. Rather, the term *historical act* recognizes that acts occur not just in a current situational context, but also as part of a stream of purposive acts in an individual life. In practical terms, contextualists (1) focus on the whole behavioral event, (2) are continuously sensitive to the role of context in understanding the nature and function of this event, and (3) maintain a firm grasp on a pragmatic truth criterion. Contextualism is commonly distinguished from mechanism, formism, and organicism as other broad philosophical approaches.

To contextualistic psychologists, a psychological act-in-context cannot be explained by an appeal to actions of various parts of the organism such as its brain or muscles. Legs do not go shopping, brains do not go hunting, and penises do not make love. People do these things, and people are integrated organisms. This does not mean that information about the operation of the brain or other parts of the organism are not relevant, but that the whole event is always primary and reductionism and expansionism are rejected. Contextualism is applicable at all levels of analysis. If one were to become interested in the action of a part of the organism (say, the brain) then this would become the new whole and all else would be context at this new level of analysis. What is learned at one level of organization will not, however, fully explain events at other levels of organization.

Each participant in a whole event defines the qualities of the other participants, much as the front of a coin implies a back and vice versa. For example, going shopping implies a place to go from and to, a reason to go, a method of going, and future events that shopping will enable. All of these facets working together are the whole event, and none can be examined out of context and be fully understood. The legs may move in a particular fashion as one goes to the store, but moving legs are not "shopping," and the same leg movements may participate in completely different acts in other contexts (e.g., dancing, exercising). To a contextualist, the whole behavioral event cannot be built up from its components, because qualities of the whole event exist only in the totality.

What creates the whole event is the purpose of the behaving organism and, at another level, the purpose of the person doing the analysis. In other words, units of action are entirely functional. It is not assumed that there are "true" units, only useful ones. The universe is the ultimate context, but the universe is not something that can be described, so all units are taken to be convenient analytic fictions. The specific contextual or behavioral features to be abstracted are those that contribute to the achievement of the goals of the therapist or scientist in doing an analysis.

The truth criterion of contextualism emerges from the core analytic unit itself: *successful working*. Going shopping implies a place to shop, and when that place has been reached and shopping has occurred, the act is complete. Similarly, a pragmatic truth criterion implies a goal to be reached, and when that goal is reached the analysis is complete. Since successful working is the means by which contextualists evaluate events, and goals allow this criterion to be applied, analytic goals themselves cannot ultimately be evaluated or justified. They can only be stated. To evaluate a goal via successful working would require yet another goal, but then that second goal could not be evaluated, and so on *ad infinitum.*

Logically this means there are as many forms of contextualism as there are sets of scientific goals. Nevertheless, in psychology we can organize contextualists into two rough groups. *Descriptive contextualists* seek a full and personal appreciation of the participating factors in a whole event. They are like historians, wanting to appreciate a unique historical event by examining closely all the strands that make up the whole story. Dramaturgy, hermeneutics, narrative psychology, interbehaviorism, feminist psychology, and social constructionism are all examples of this type of contextualism. *Functional contextualists* seek the prediction and influence of events as an integrated goal. Contextualistic behavior analysis, some forms of Marxist psychology, and some forms of psychobiological thinking are examples.

The choice of a goal in contextualism is pre-analytic. It is a means of analysis, not the result of analysis. Thus, neither descriptive nor functional contextualists can claim that their goal is the "right" goal. But we can examine what happens when these different goals are adopted.

Consider, for example, the environmentalism that is so characteristic of behavior analysis. Initially this focus seems dogmatic, since obviously behavior influences the environment as much as environment influences behavior. The dogmatism is removed when one realizes that the contextual features to be abstracted in any contextualistic analysis are those that contribute to the achievement of the goals of the analysis. Functional contextualists want analyses that achieve prediction and influence as an *integrated* goal. Only contextual features that are (1) external to the behavior of the individual being studied and (2) manipulable, at least in principle, could possibly lead *directly* to behavioral influence as an outcome. Verbal analyses generate rules for people, not rules for the world. To accomplish prediction *and* influence, rules must start with the environment, in the sense of the "world outside of the behavior," because that is where the consumers of these rules are. The environmentalism in behavior analysis is thus made more coherent (and nondogmatic) when it is seen as part of a particular contextualistic system.

In the hands of a contextualist, mundane clinical statements can lead to unusual outcomes. For example, suppose a client says "I can't leave my home or I will have an anxiety attack." A more mechanistic therapist might wonder

why the person is anxious or how the panic can be alleviated. Among several other steps, contextualistic clinician might (1) look for the larger contexts that are implied by this formulation (e.g., that anxiety is bad); (2) examine the context in which the client would say such a thing (e.g., what the person is accomplishing in therapy by this speech act—is the person asking for support, explaining dependence, etc.?); (3) look for contexts that exist or could be created in which panic and staying home are unrelated events (for example, if anxiety was no longer avoided, would anxiety still lead to staying inside?); or (4) see if there are parts of this statement that could be supported therapeutically, and so on. Several new forms of intervention in the behavioral and cognitive therapies (e.g., Acceptance and Commitment Therapy, Functional Analytic Psychotherapy) are contextualistic, taking advantage of the new light contextualism casts on old issues.

CONTROL THERAPY

Control therapy is an integrated approach to psychotherapy and health care that combines theory, research, and practice. It is based on the premise that issues of control (e.g., fear of loss of control, desire for control, power struggles) underlie most concerns brought to therapy. A reliable and valid standardized psychological assessment inventory (the Shapiro Control Inventory, or SCI) was developed to both measure the theory and provide an individual client "control profile." Control-based therapeutic techniques, including an assertive change mode of control and an accepting/yielding mode of control, are matched to the client's control profile and taught as interventions. The theory, test construction, and interventions have been developed and empirically tested over a period of 25 years involving research and clinical work with thousands of individuals in over a dozen countries.

A Unifying Theory of Control

The theoretical basis of control therapy builds upon and integrates several literatures, including self-efficacy; learned helplessness; optimism; competence; dyscontrol; reactance; will to meaning; will to superiority; cybernetic feedback models and disregulation; internal and external locus of control; self-determination; and self-control/delay of gratification.

Thus, control theory is based on an unifying bio-psychosocial theory of human control and self-control and has three postulates: (1) All individuals want a sense of control in their lives; (2) there are healthy and unhealthy ways by which they attempt to gain or regain that sense of control; and (3) there are individual differences in control profiles of individuals and in how they face this central issue of maintaining a healthy sense of control in their lives.

Developing a Client Control Profile: Assessing the Theory

A client control profile is based on clinical assessment with the SCI, which has undergone extensive reliability and validity testing (including an investigation of neurobiological correlates of control using positron emission tomography). The 187-item, nine-scale SCI inventory is a clinically reliable and valid multidimensional instrument that measures four primary and interrelated components of clients' control profiles: (1) desire for control (i.e., where they want control and why they want it); (2) current sense of control in both general and specific domains; (3) the modes by which they seek control (assertive/change and yielding/accepting); and (4) use of both self and other agencies in gaining control. Research shows that this method of assessing client control profiles is the most sensitive inventory yet devised to differentiate among clinical disorders and between clinical and normative populations.

Assessment also includes methods for listening to clients' speech—including the clients' narratives (their "control stories"), control-related beliefs and assumptions, and assaults to their sense of control—and identifying and monitoring domains where they feel a lack of control.

Control-Based Interventions

Control therapy consists of an 8- to 12-week step-by-step treatment program that involves defining the area of concern, performing assessment, monitoring, goal setting, determining the appropriate strategies, teaching the strategies, and performing evaluation.

Therapeutic interventions involve detailed and well-defined clinical instructions for matching treatment strategy to the client's control profile, thus offering both standardized, replicable techniques and providing flexibility and sensitivity to each client's individual needs and style.

Based on the goal selected, individually tailored cognitive and behavioral strategies are utilized to help clients regain a sense of control through one or both of the positive modes of control. The assertive/change mode of control, which has historically been emphasized by Western scientific psychology, involves having individuals learn to identify, monitor, and gain active control of those aspects of their lives that are or should be amenable to change.

The yielding, accepting mode, which has historically been emphasized by non-Western philosophical and psychological traditions, helps clients learn the value of surren-

dering, accepting, and letting go with serenity (i.e., without feelings of helplessness or resignation) of those aspects of their lives that are not under personal control, or of inappropriate active control efforts. Practical instructions in each mode are explained, as well as ways to integrate and achieve balance between the two positive modes.

A Control-Based View of Psychological Health: Suboptimal, Normal, and Optimal

Traditional Western psychology argues that loss of control and learned helplessness are unhealthy and suboptimal. Normal control is defined as gaining control (which even includes an illusion of control) and is equated with mental health. This traditional view argues that instrumental control is good, and that the more control, the better.

The theory, research, and practice of control therapy agree that "normal" control is better than suboptimal. However, normal control strategies (e.g., external attributions for failure) can also be problematic. They can keep individuals from being aware of the unconscious, reflexive, and reactive nature of many of their control desires and efforts; they are often insular and self-serving; and they can keep people from learning about their mistakes.

Therefore, a concept of optimal control is needed. Optimal control, according to Control Therapy, involves the following:

- Increased conscious awareness of one's control dynamics, including affective, cognitive, and somatic experiences, in order to learn when and how desire and efforts for control are expressed; when control beliefs, goals, desires, and strategies are reflexive, limiting, and potentially destructive; and when they should be increased, decreased, or channeled
- A balanced and integrated use of assertive/change and yielding/accepting modes of control matched to situation and goals, desires, and temperament
- The ability to gain a sense of control from both self (self-regulation of cognitions, affect, and behavior) and others (including religious and spiritual beliefs)

Benefits of Control Therapy

Control therapy has been shown to be effective in both assessment (sensitivity and specificity) and treatment (clinical outcome) with a wide range of mental disorder diagnoses and health-related concerns. Clinical areas investigated include Generalized Anxiety Disorder, panic attack, depression, borderline personality, eating disorders, and adult children of alcoholics. Control issues have also been investigated in type-A individuals with myocardial infarction, women with breast cancer, and individuals at high cardiovascular risk.

There are several advantages to control therapy and the unifying theory upon which it is based. First, a unifying theory helps clinicians understand control as a central component underlying all schools of therapy; the analytic view that humans are governed by unknown and uncontrolled forces; the cognitive-behavioral schools' emphasis on self-control; and the humanistic or existential focus on personal choice, individual freedom, and self-determination.

Second, in addition to the theory's universality and parsimony, it also can be operationalized, thereby providing an empirical foundation for assessing a client's control profile. Based on individual variations in control profiles, specific techniques can be matched to client needs and clinical problem.

Third, drawing from both Eastern and Western psychological traditions, control therapy involves specific assertive/change and yielding/accepting modes of control intervention techniques, and the matching of these techniques to a client's control profile, goals, and clinical problem.

Finally, control therapy articulates a control-based vision of mental, physical, and interpersonal health involving suboptimal, normal, and optimal control profiles. Thus, although control therapy was designed to specifically address individual mental and physical health problems, it can also be used as a means to help promote growth, including intrapersonal, interpersonal, and even societal health, healing, and well-being.

CONSTRUCTIVIST PSYCHOTHERAPY

Constructivism refers to a group of theories (originally stemming from George Kelly's personal construct theory) holding the philosophical position that so-called reality is, in some ways, created by persons. Rather than imposing some objective truth on persons seeking help, constructivist therapists attempt experientially to grasp the lived reality of each client. Constructivist therapy is a cocreated experience between therapist and client, mutual experts on different aspects of the reality being created between them. This relationship is more egalitarian and client-empowering than approaches in which the more powerful therapist imposes diagnostic and treatment "realities" on the less powerful client. Consistent with Kelly's theory, constructivist psychotherapy can be seen as a part of the broader group of humanistic, existential, and postmodern therapies.

While all constructivists agree that reality cannot be known directly, different theoretical groups disagree on the exact nature of the relationship between the person and the world. *Radical constructivists* argue that one cannot even speak of a reality outside of the meanings the person has created. *Social constructionists* might argue that we are saturated with meanings created by cultures and imposed upon us. Occupying a middle ground, *critical constructivists* believe that meanings are cocreated in the dynamic interaction between the person and the world.

Although there are numerous specific approaches (a few of which are described later), constructivist therapies generally share certain attitudes about therapy. Most constructivists will listen to clients with the assumption that everything the client says is true in the sense of revealing important aspects of the client's experiential meaning system (Kelly's *credulous approach*). There is a respect for contrast, oppositionality, or the dialectic in meaning making. Most constructivists also are attuned to making therapy a safe place for clients to experience life, explore, and grow, and they emphasize seeing the client as a *process of meaning creation* rather than a static entity composed of specific meanings. The client's process of construction is seen as active as opposed to reactive and underscores the agency of the person, again emphasizing the humanistic and existential roots of the approach.

Different constructivist therapists employ these attitudes in different therapeutic approaches. In Kelly's *fixed-role therapy,* for example, the client first writes a character sketch that is open, revealing, yet sympathetic. This sketch is written in the third person, from the perspective of a friend who might know the client most intimately. The therapist and client then cocreate an alternate sketch for the client to enact, typically for a 2-week period. Fixed-role therapy is viewed as a failure if the client sees it as a behavioral prescription; it is designed to free the client to experiment with alternative ways of experiencing life.

Experiential personal construct psychotherapy (EPCP) is based upon the relational, experiential, and existential foundations of personal construct psychology. EPCP construes persons as simultaneously needing and being terrified of depths of emotional closeness. On the one hand, such intimate relationships can affirm the meanings that have formed the foundation of our existence. On the other hand, we can experience devastating disconfirmation in intimate relationships. Clients then struggle with needing to connect with others, risking terror to gain profound richness, versus retreating from intimacy, buying safety at the cost of the empty objectification of self and others. Therapeutic growth can occur if the therapist experiences *optimal therapeutic distance,* a blending of profound connection and separateness, when the therapist is close enough to feel the client's experience yet distant enough to recognize those feelings as the client's and not the therapist's own.

Other constructivist therapists employ narrative approaches to therapy. These therapists believe that narratives give meaning and continuity to the lived experience of clients. Gaps, incompleteness, and incoherence in the client's life story may indicate struggles in creating an integrated experience of self-in-the-world. Goncalves illustrates constructivist narrative therapy with his "moviola" technique, in which the therapist's attention scans the settings of a client's life, much like a camera in a movie. The therapist can zoom in on a detail or back off and get a more panoramic view. For example, a therapist might start by having the client describe the entire room in which he or she was abused. Eventually, the therapist might help the client see in detail his or her face, filled with fear and horror, while the abuse occurred. Because people innately create meanings to understand their experiences, the experience of re-viewing the abuse with an empathic therapist allows for new constructions to be created. These newer meanings, in turn, allow for newer experiences as clients' lives move into the future.

Depth-oriented brief therapy (DOBT) applies constructivist principles to help clients understand and engage in radical change in a very short-term treatment. DOBT understands the symptom as painful because of the ways it invalidates important aspects of our experience. At the same time, there are other constructions, often at a lower level of consciousness, making the symptom absolutely necessary for the client. DOBT uses specific experiential techniques to help the client gain access to these deeper meanings. The client then can more consciously decide whether to keep or abandon these more unconscious meanings.

Constructivist therapy has been used with a wide range of problems, from mild adjustment issues to the most severely disturbed clients. It has been used with specific symptoms (e.g., stuttering, obesity, bulimia, posttraumatic flashbacks) as well as more general life distress. It also has been useful with young children as well as elderly clients. Specific constructivist techniques have been developed for family therapy (e.g., systemic bow-ties to help each client understand how their actions, based upon their deepest fears, confirm the deepest fears of other family members).

There have been numerous methodologically sound studies exploring the effectiveness of constructivist therapies across different countries, ages, and types of problems. Effect sizes for client change in these studies were at least as large as those reported in the cognitive-behavioral and psychoanalytic literature. In other words, good constructivist therapy respects the lived experiences of persons and has been empirically supported by studies that meet the most rigorous of experimental criteria.

CONVULSANTS

Convulsants are substances that induce seizurelike paroxysmal behaviors by producing patterns of electrical activity in the brain that resemble those seen in human epilepsy.

Epilepsy is characterized by recurring episodes in which the electrical activity of many thousands of neurons becomes abnormally elevated and pathologically synchronized. This discharge interrupts normal brain function and leads, in some forms of epilepsy, to alterations in behavior (seizures). Seizures come in many varieties, ranging from brief, barely detectable losses of consciousness in what are called absence or petit mal epilepsies, to uncontrollable tonic-clonic contractions of large muscle groups in the so-called grand mal epilepsies. The behavioral manifestations and severity of the seizure reflect primarily the size and localization of the abnormal electrical discharge.

One remarkable aspect of the human epilepsies is the diversity of underlying etiological factors, including perinatal trauma, brain infection, drug and alcohol withdrawal, tumors, and stroke. Our current understanding of epilepsy is that epileptiform brain activity and the behavioral seizures produced by that activity arise as the symptom of some underlying brain pathology. Perhaps it not surprising, therefore, that an incredibly diverse group of chemical substances can produce convulsions when given centrally or applied directly to brain tissue.

The study of the mechanism of action of convulsants has led to the formulation of one of the more enduring hypotheses of the generation of epilepsy (Traub & Miles, 1991). There seems to be a delicate balance between the strength of inhibitory and excitatory synaptic transmission in the brain. Any disturbance in this balance that favors excitation will lead to the uncontrolled spread of excitation between cells so that their discharge becomes rapidly synchronous. In this sense, epilepsy is a disease of populations of cells, rather than individual cells. In fact, not all brain regions are equally likely to be identified as sites of epileptiform discharge in patients, and not all brain regions are equally sensitive to convulsants. It is thought that the ability of a convulsant to trigger seizures in a given brain region depends on a number of factors. First, the convulsant's appropriate target must be present. The convulsant strychnine, for example, will be inactive in nuclei lacking glycinergic inhibition. Second, the necessary neuronal circuitry must be present. In particular, there must be local excitatory axon collaterals so that excitation can spread between cells. These connections are particularly prominent between pyramidal cells in the hippocampal formation and neocortex—two regions that are highly sensitive to most convulsants and in which epileptic discharge is typically initiated in human epilepsy patients. Finally, some output connections capable of influencing behavior and/or consciousness must be present.

Several of the most widely used and better understood convulsants are listed in Table 1 (for reviews see Fisher, 1989; Löscher & Schmidt, 1988), and they have been classified by their actions on the balance of excitatory and inhibitory synaptic transmission, when known. It should be noted that the patterns of seizures and electrical abnormalities are not the same for all convulsants and may vary for any one convulsant depending on where and how the substance is applied.

Convulsants That Decrease Inhibition

Much of our understanding of the cellular basis of epilepsy comes from the application of convulsants to the brain, in whole animal experiments and, more recently, to isolated slices of brain tissue maintained ex vivo. Penicillin, the first widely used convulsant, is a weak antagonist of the recep-

Table 1. Widely Used Convulsants and Their Mechanism of Action

Class of Action	Target System	Mechanism of Action	Examples
Decrease inhibition:	1. g-aminobutyric acid	a. Receptor antagonists	penicillin, bicuculline, picrotoxin,
		b. Synthesis inhibitors	methoxypyridoxine, isoniazid, 3-mecaptoproprionic acid
		c. Benzodiazepine receptor	inverse agonists
		d. Release inhibitors	opioid peptides
	2. Glycine	a. Receptor antagonists	strychnine
Enhance excitation:	1. Excitatory amino acids (e.g. glutamate)	a. NMDA receptors	magnesium-free saline
		b. non-NMDA receptors	kainic acid
		c. Potassium channel blockers	tetraethylammonium, 4-aminopyridine, various peptide toxins
	2. Acetylcholine	a. Receptor agonists	pilocarpine
		b. Cholinesterase inhibitors	soman
Unknown		a. Neurotoxins	cholera toxin, tetanus toxin
		b. Injury/Trauma	alumina hydroxide, cobalt
		b. CNS Stimulant	p entylenetetrazol

tors for the predominant brain inhibitory neurotransmitter, γ-aminobutyric acid (GABA). More potent antagonists, such as bicuculline and the ion channel-blocker picrotoxin, are now more typically used. Seizures and epileptiform discharge can also be elicited by blocking the synthesis or release of GABA. In addition, substances active at modulatory sites on GABA receptors can also exert convulsant activity, such as inverse agonists of the benzodiazepine receptor.

Convulsants That Increase Excitation

Substances that directly or indirectly increase excitation are powerful convulsants. For example, application of saline containing a lower than physiological concentration of Mg^{2+} relieves the normal block of the ion channels gated by N-methyl-D-aspartate (NMDA)–preferring excitatory amino acid receptors, and thus considerably enhances the synaptic excitation of cells. Application of kainic acid, an agonist of non-NMDA excitatory amino acid receptors, is also widely used to trigger seizures in whole animals, by injection either into the cerebral vesicles or directly into the tissue. The release of endogenous excitatory amino acids can also be triggered by increasing the excitability of neurons with substances that block repolarizing K^+ conductances. Neurons have perhaps hundreds of such K^+ conductances, and numerous antagonists of these channels are effective convulsants, including tetraethylammonium, 4-amminopyridine, and various naturally occurring peptide toxins. Finally, modulators of central cholinergic synaptic function are also employed as convulsants, including direct agonists such as pilocarpine as well as acetylcholinesterase inhibitors, and are believed to act by increasing neuronal excitability.

Other Convulsants

Although the mechanism of action of these convulsants fits well with the hypothesized balance of synaptic excitation and inhibition in epilepsy-prone brain regions, it is less well understood how other important convulsants exert their effects. Cholera toxin is an activator of adenylate cyclase and may therefore trigger seizures by mimicking any of the many cellular actions of cAMP and cAMP-dependent protein kinase, including reduction of K^+ conductance and facilitation of transmitter release. Tetanus toxin inhibits the release of both excitatory and inhibitory neurotransmitters. Epileptiform activity elicited by focal application of alumina hydroxide or cobalt has been used as a model for posttraumatic epilepsy, although the mechanisms underlying seizure generation remain unclear. Pentylenetetrazol is a powerful and widely used convulsant whose mechanism of action is also unknown.

CORRELATION METHODS

Correlation and regression deal with (1) how closely variables are related, and (2) the prediction of one variable from another. If we are dealing with *bivariate* (i.e., two variables) correlation and regression, the correlation coefficient assesses the degree to which the variables X and Y have a linear relationship, when standardized; and regression refers to the prediction of one variable—say, Y—from another—say, X—using a linear equation of the form

$$\hat{Y} = b_0 + b_1X$$

The Correlation Coefficient

The Pearson product-moment correlation coefficient for X and Y is most easily thought of as the mean of the summed cross-products of the z-scores of X and Y; that is,

$$r_{XY} = \frac{1}{N}\sum_i z_{X_i}z_{Y_i} \quad \text{where} \quad z_{X_i} = \frac{X_i - \text{mean of } X}{\text{standard deviation of } X},$$

although it can be written in many other forms. This coefficient takes on a value of +1 if all of the data points (X, Y) fall exactly on a straight line with a positive slope, so that Y increases as X increases, and –1 if they all fall on a straight line with a negative slope. If there is no linear component to the relationship between Y and X, the correlation coefficient will have a value of close to 0.

The size of the correlation coefficient stays the same if either or both of X and Y undergo linear transformations in which each value is multiplied by a constant and another constant is then added to or subtracted from the product. Therefore, the correlation coefficient stays the same if units are changed, so that the correlation between height and weight would be the same if height was measured in inches or meters.

The correlation coefficient is often misinterpreted. Among issues to consider are the following: First, the correlation coefficient is an index of *linear* relationship, not relationship in general; therefore, a correlation of 0 does not rule out the existence of a systematic nonlinear relationship between the variables. Second, if X and Y are correlated, it does not necessarily follow that there is a direct

causal relationship between them; the correlation could occur because of the influence of other variables. For example, among elementary school students, vocabulary size is strongly correlated with height because both are related to chronological age. Finally, although the correlation coefficient is an index of linear relationship, unless the variances of X and Y are equal, r doesn't by itself provide information about the nature of the best-fitting linear function. In particular, the slope, or rate of change, of Y with X is given by

$$b_{YX} = \frac{r_{XY} s_Y}{s_X},$$

that is, the correlation coefficient multiplied by the ratio of the standard deviations. So if in two groups the rates of change of Y with changes in X are the same, the correlations may well be different if there is more variability in the values of X and Y in one group than in the other. For this reason, r is often referred to as a *sample-specific* measure.

Correlational Versus Experimental Research

A distinction is often made between experimental and correlational (or observational) research. In true experiments, independent variables are manipulated; that is, the assignment of subjects to the level of the independent variable is under control of the experimenter. If the experiment is conducted properly, it is possible to make causal statements about the effect of the independent variable on the dependent variable. In correlational studies, values are simply observed, no attempt is made to manipulate the independent variables, and it is not possible to make causal statements. Suppose we wanted to compare the effectiveness of two methods of teaching reading. If we simply measured the reading ability of students taught by the two methods, we could not be sure whether any differences were due to the teaching methods themselves or to other factors "correlated" with the use of the methods. Perhaps one of the methods tended to be used more in neighborhoods that had schools with smaller class sizes and families who provided more support to students.

Some Other Correlation Coefficients

A number of other correlation coefficients are also encountered. Some of these are simply the Pearson coefficient applied to specific classes of data. Examples are the *Spearman rank-order correlation coefficient,* which is just the Pearson coefficient applied to ranked data, and the *point-biserial correlation coefficient,* which can be thought of as the regular Pearson coefficient applied to data in which Y is continuous and X is dichotomous (i.e., X takes on only two possible values). The so-called *phi coefficient* is just the Pearson coefficient applied to data in which both X and Y are dichotomous.

Several other measures make assumptions of underlying normality to estimate what the correlation would have been if one or both variables had not been artificially dichotomized. Suppose we wish to correlate math and verbal ability. Assume we have normally distributed scores on a verbal ability test but all we know about math ability is whether or not each student passed the test. If we assume that math ability is normally distributed, we can generate the biserial correlation coefficient, which is an estimate of what the correlation coefficient would be if we had continuous scores on both dimensions. The tetrachoric correlation coefficient results if we apply the same logic to two dichotomous variables.

Multiple Correlation

Suppose we wish to predict a criterion variable Y from a number of predictor variables $X_1, X_2, \ldots X_p$. For example, we may wish to predict a measure of success in graduate school on the basis of undergraduate grades and verbal and quantitative Graduate Record Exam scores. Using the procedures of multiple regression, we can find the equation of the form

$$\hat{Y} = b_0 + b_1 X_1 + b_2 X_2 + \ldots + b_p X_p$$

that optimally predicts Y. The multiple correlation coefficient, $R_{Y12..p}$, is simply the Pearson product-moment correlation coefficient between the predicted and actual Y scores.

COUNSELING

The term *counseling* has both a generic and a more specific meaning. Generally speaking, counseling represents a set of problem-solving actions—developing a working relationship, assessing the problem, initiating behavior change, maintaining change, and evaluating the outcomes. These generic actions are used by "counselors" working in a variety of professions, including business, law, education, health, and so on. Thus, we have financial counselors, legal counsel, academic advisors, and nutritional consultants—all of whom are identified as doing counseling. From a more specific stance, counseling also represents a professional identity and tradition with ethical codes, licensure proce-

dures, scholarly journals, professional organizations, and academic requirements. Counseling in the professional sense and as the topic of this narrative has been associated with education and medicine, which provide the historical traditions through which counseling has evolved. Counseling as an educational intervention has been associated with schools and guidance programs, whereas counseling as a more medically oriented intervention has become interchangeable with psychotherapy practiced in clinical settings. While such diversity is viewed as a strength by some, others note the lack of consensus reflected in professional identity problems.

Counseling as Education

Counseling as education—or guidance, as it is often called—is related to the historical use of the term *counseling.* Dictionary definitions of counseling emphasize giving advice and exchanging information. Since the earliest times, people have sought advice and counsel—from Old Testament prophets, Greek philosophers, and ancient healers. Although such earlier antecedents can be identified, guidance developed in the industrialized Middle West and East. The merger of vocational guidance and psychological testing established an important foundation of counseling. Before the development of testing, vocational guidance relied on vocational education that stressed occupational information and advice. With the development of testing in the areas of ability, interests, occupations, and personality, vocational guidance obtained a scientific means to realize its commonsense notion of improving the worker-occupation relationship. As articulated by the leaders of vocational guidance, perhaps most persuasively by Frank Parsons in *Choosing a Vocation,* worker-occupation relationships depended on a suitable match between the worker and the job. This match was predicated on the ability to gather accurate information about the individual, his or her abilities and interests, and the job. Scientific methods helped transform guidance workers into professionals, established the respectability of vocational counseling, and facilitated its acceptance by public institutions such as the schools and, later, the Veterans Administration. Such a transformation was largely carried out at the University of Minnesota through the pioneering work of Donald Patterson and his colleagues and students, especially E. G. Williamson.

In the 1950s and 1960s, counseling as guidance—while less popular than psychotherapy—was stimulated by the development of professional organizations (e.g., American Personnel and Guidance Association and now the American Counseling Association) and the reemergence of the importance of schooling (with Russian Sputnik I) and work (with the Vocational Rehabilitation Act of 1954). As a result, there was a great demand for school counselors (spurred by the National Defense Act of 1958) and rehabilitation counselors. In response, professional organizations lobbied for funds and later established accreditation programs (e.g., the Council for the Accreditation of Counseling and Related Programs) for the preparation of counselors. Through their respective journals, the concerns of counselors were given a voice.

On the other hand, another organization with members representing the guidance tradition—originally the Division of Counseling and Guidance, in 1952 renamed the Division of Counseling Psychology (American Psychological Association) and now, the Society of Counseling Psychology, a division of the American Psychological Association—competed for psychological services (e.g., the Veterans Administration). These activities contributed to the further decline of the guidance tradition and to a separation of counseling psychologists with doctoral-level training from school and rehabilitation counselors with subdoctoral-level training.

During this time period, advances in social sciences brought significant conceptual developments (self-concept theory, stage theory) that transformed vocational guidance into career development (with the work of Donald Super, John Holland, Anne Roe, and others). Today the emphasis is on addressing the theoretical and empirical inadequacies of this tradition that neglected the roles of gender, race, class, sexual orientation, and disability. New programs are being developed to address these deficiencies, such as the school-to-work transition movement.

Counseling as Therapy

Around 1940, the dominance of the guidance model began to erode; by the end of the decade it was replaced by psychotherapy, an intervention often associated with a more medically oriented setting. A number of factors contributed to the decline. Part of the downfall coincided with social changes brought on by the end of the Depression and the beginning of World War II. People were confronted with rapid social change that seemed to broadly affect their lives.

Effects went beyond educational or occupational problems as people sought help with all types of personal adjustment issues. In this Age of Psychotherapy, the publication of Carl Rogers's *Counseling and Psychotherapy* was important. Rogers, trained as a clinical psychologist, brought psychotherapy from the medical clinic to nonmedical practitioners. He transformed therapy as a medical intervention by framing therapy in terms of a humanistic philosophy, an approach more congenial to counselors.

This psychotherapy tradition represented by Rogers had multiple sources. Perhaps the central experience for Rogers was his work with clients. From these experiences, Rogers formulated and reformulated his approach to counseling and psychotherapy. Although there have been changes and shifts of emphasis, the basic outlook has been a person-centered approach in which the self-determination capacities of the client are the focus of attention, concern, activity, and acceptance conveyed through a therapeutic relationship. Like Parsons's conceptual contribution to the guidance tradition, Rogers focused on individual assets. Both of these

traditions, guidance and therapy, highlight the worldview of counseling, a focus on strengths rather than pathology.

Since Rogers, there have been numerous counseling and psychotherapy approaches advanced. As the twenty-first century begins, there is renewed emphasis on counseling that works, with most attention focusing on competing models of treatment—cognitive-behavioral treatment versus a common-factors position. For psychotherapy, the challenge in a rapidly changing health care market is to document the effectiveness of counseling practices, especially the validity of our treatments for racial and ethnic minorities.

Challenges

Up to this point, counseling has been seen as evolving as a field through vocational guidance and psychotherapy. Although *counseling* often has multiple meanings, it continues to represent a disciplined mode of action of working with people. Counseling faces numerous future challenges, but diversity and managed health care appear to have the largest potential for influencing the nature of counseling in the new millennium. The growing diversity of our population and the inadequacy of our traditional counseling world view have stimulated a multicultural revolution. Beginning with the unmet need for counseling women, counselors have struggled to develop approaches that are effective with various oppressed groups in our society (racial and ethnic minorities; gay, lesbian, bisexual, and transgender-identified individuals; persons with disabilities). The traditional counseling competencies—relationship, assessment, interviewing, intervention, and research skills—need a cultural transformation from a set of competencies reflecting a universal cultural myth to a set of cultural practices appropriate to a worldview of multiple perspectives. The other challenge, managed care, has focused attention on examining the effectiveness of counseling practices. In putting these challenges together, the big question is not if counseling works, but if counseling works for neglected groups of our society.

COUNSELING PSYCHOLOGY

Counseling psychology has undergone significant developments since its formal inception as a distinct helping profession in 1946. Originally devoted to assisting individuals in the search for appropriate occupations, it broadened into a profession that assists relatively intact persons in maximizing their developmental potential in all areas of their lives. In doing so, it makes use of a wide variety of sophisticated psychological interventions designed not only to assist people in adjusting to their environment, but also to modify environments to make them more suited to human needs.

Definitional Models of Counseling Psychology

The definition of counseling psychology has consisted of several emphases that distinguish it from related helping professions. First, counseling psychology has consistently followed an educational rather than a clinical, remedial, or medical model. Clients (not patients) are viewed as normal individuals who need assistance in coping with stresses and tasks of everyday life. The task of the counseling psychologist is to teach clients coping strategies and new behaviors that they can use in making maximum use of their already existing resources or in developing more adequate resources.

Other methods may be used for reeducating clients besides the dyadic interview. Thus, counseling psychologists may lead groups designed to enhance the lives of each of the members, or they may design and conduct workshops on various aspects of life planning, such as assertion skills or communications skills. The counseling psychologist may intervene in the client's immediate environment to facilitate client change and growth, and he or she may relate to the client in real-life situations in addition to an office setting.

Counseling psychology's educational base is seen most clearly in public schools and in college and university counseling centers. There, however, the counselor's role has broadened from an almost exclusive concern with the vocational and educational guidance of youths to an increasing focus on the creation of a total educational environment conducive to learning. In the process, counselors find themselves doing not only vocational counseling but also personal and emotional counseling in an attempt to maximize students' receptivity to education. Counselors may also act as consultants with faculty and administration to help create a total school environment that facilitates learning. School counselors generally are trained at the master's degree level, while college and university counseling psychologists typically possess a doctorate degree.

Counseling psychology stresses a developmental model. It attempts to assist clients in achieving their optimal development and in removing blocks to normal growth.

Counseling psychology has advocated preventive approaches to developmental problems in addition to, but not to the exclusion of, remedial approaches. The strategy in prevention is to identify individuals, groups, or settings that, according to theory and research, are seen as being particularly at risk, and to intervene with appropriate individuals or in appropriate settings *before* a crisis occurs. This is analogous to public health measures designed to prevent the outbreak of disease rather than to cure it.

Counseling psychology, alone among the helping professions, pays particular attention to the role of occupation in the lives of people. Indeed, the profession derives much of its identity from the vocational guidance movement. With the post–World War II rise of affluence and the decline of

the work ethic as a source of personal and societal values, counseling psychology broadened its aim to include personal development in areas other than work. The profession's methodology has likewise become more sophisticated, moving from a relatively straightforward one-time matching of persons and jobs to a consideration of psychological needs fulfilled by work, the selection of different occupations throughout the life span as a function of developmental stages, the differing career patterns of men and women, and an exploration of the meaning and value of work in relation to other activities such as leisure.

Professional Identity of Counseling Psychology

As counseling psychology evolved from its original base of vocational guidance, it overlapped with other helping professions. Thus, as psychotherapy increasingly was practiced by counseling psychologists without reference to occupational selection, the overlap with clinical psychology grew. As counseling psychologists intervened in the client's network of social relations, their function overlapped with that of social workers. Meanwhile, clinical psychologists moved increasingly out of the mental hospitals, away from assessment of mental functioning as a primary activity, and toward a greater involvement with relatively intact individuals. Similarly, social workers moved away from case management and toward therapeutic counseling. There has thus been simultaneous movement of the three largest helping professions toward one another, resulting in a blurring of previously distinct role definitions and functions.

Exacerbating the identity problem is the historical linkage of counseling psychology with colleges of education, due in large part to the original mission of counseling departments to train school counselors. As, on the one hand, counselor education broadened in scope into counseling psychology and, on the other hand, vocational guidance became increasingly psychologically sophisticated, counseling psychology programs were often caught between education and psychology. The result is that the majority of counseling psychology programs approved by the American Psychological Association currently are located in colleges of education rather than in departments of psychology. Although this makes sense in terms of the educational model of the profession, among counseling psychologists it has resulted in a split loyalty between the field of counselor education, which may not be psychologically oriented, and the field of applied psychology, which may follow a remedial, quasi-medical model. As the issues of licensing and credentialing, specialty guidelines, and third-party payments become important, counseling psychologists are being forced to choose between education and psychology as their main knowledge base and source of professional identity. As a result, counseling psychology programs have taken on a greater emphasis on training in basic psychology, and the gulf between counseling psychology and counselor education appears to be growing.

Theoretical Models of Counseling Psychology

The original Minnesota model of vocational counseling began during the 1930s with Edmund G. Williamson in the Student Counseling Bureau at the University of Minnesota and served as a model for most later university counseling centers. This model was basically a rational decision-making process in which test interpretation figured prominently and that resulted in an educational or occupational selection. With the rise of the psychotherapy movement, counseling psychology models focused more on the *process* of the counseling relationship than on the *outcome*.

Two theoretical models in particular—the decision-making and the counselor social influence models—warrant further discussion, as they represent a unique contribution of counseling psychology to applied psychology. Decision-making counseling involves the translation into the counseling process of the concepts and practices underlying decision theory, and in general it attempts to teach clients, either individually or in groups, overt procedures and strategies for effective decision making. The decision-making model is especially suitable for vocational and career counseling, as illustrated by Mitchell, Jones, and Krumboltz in *Social Learning and Career Decision Making*. Counseling psychology's stress on prevention is nicely illustrated by the decision-making model; formal classes as well as other methods of teaching decision-making skills have been used to teach these skills to potentially high-risk populations *before* major decisions must be made.

Problem solving is closely related to decision making. In *Problem-Solving Counseling,* David Dixon and John Glover have integrated the pragmatic problem-solving methodology that characterizes a number of counseling psychology approaches with the research and conceptual literature on problem solving. Both decision-making and problem-solving integrations represent a movement to include cognitive dimensions along with behavioral counseling.

The social influence model of the counseling process was originally proposed by Stanley R. Strong in the late 1960s. Strong drew on the interpersonal influence literature in social psychology to conceptualize the counselor's influence over the client as a result of the former's perceived expertness and credibility. Much research has since been done regarding the behaviors that contribute to counselor social influence; the conditions under which counselor social influence can be maximized; the relationship of social influence measures to other measures of counseling process and outcome; and social influence as a function of specific counselor and client attributes such as race, sex, and social class. Currently, social influence is one of the most influential models of the counseling process.

Research In Counseling Psychology

Research in counseling psychology has changed over time. The largest change has been the ratio of empirical studies

to conceptual or theoretical articles; in 1954, the ratio was 1:1, although in the 1980s there were more than nine empirical studies to one nonempirical study. Another change has been in the relative proportion of outcome research to process research, the former declining to a small proportion while the latter has risen to about 25% of the total. Process-outcome research has likewise shown a substantial increase, making the journal a major publication outlet for process-oriented research in applied psychology. Reflecting counseling psychology's deemphasis on vocational counseling, the percentage of research on vocational behavior has declined somewhat over the years, although this has been offset by the increase in research relating to counseling with special populations. Finally, social influence research has accounted for a significant portion of recent issues of the journal, thus emphasizing its prominent place as a process model in counseling psychology.

The quality and specificity of research in counseling psychology have likewise increased. Studies are much more likely now to use multifactorial designs, to make use of multivariate statistics, to provide tight experimental controls in order to eliminate extraneous sources of variance, and to investigate the effects of specific interventions on specific measures of change. There has been an increasing focus on what technique used by what counselor with what client results in what outcome under what conditions.

COUNTERCONDITIONING

In 1924, Mary Cover Jones, a student of John Watson, published a paper describing the successful treatment of a fear of rabbits in a 3-year-old boy named Peter. Under Watson's supervision, she exposed the child to a caged rabbit while the boy was eating one of his favorite foods. The rabbit was at first kept at a distance but gradually was moved closer to Peter over a period of several sessions. Eventually Peter was able to pet the rabbit and allow it to nibble his fingers without any sign of fear.

Counterconditioning is a procedure in which a response to a stimulus is replaced or countered by pairing that stimulus with a new stimulus of differing valence. In the case of Peter, Jones presented the feared stimulus (the rabbit) in conjunction with a pleasant stimulus (food), with the result that the fear response was eliminated. It is important to note that the feared stimulus was introduced in a gradual fashion, to ensure that at no time was a fear response elicited that was more powerful than the response of eating. Had this occurred, the fear of rabbits would not have been removed, and a conditioned fear response to the food (or other associated cues) might have been established.

Counterconditioning is somewhat similar to extinction in the classical (Pavlovian) conditioning paradigm. Both procedures result in diminution or elimination of a response to a stimulus. However, in extinction the conditioned stimulus is presented alone without the unconditioned stimulus, whereas in counterconditioning the conditioned stimulus is presented with a *different* unconditioned stimulus.

The term *counterconditioning* has been used in two different ways, which are often confused. Letting S stand for stimulus and R for response, consider two reflexes, $S_1 \rightarrow R_1$ and $S_2 \rightarrow R_2$, where it is impossible for R_1 and R_2 to occur simultaneously. In one usage, counterconditioning is a *procedure* involving the pairing of S_1 with S_2. The result of such a procedure is usually the elimination of the weaker of the two reflexes. In the second usage, counterconditioning is an inferred *process* proposed to explain this result. This process is stimulus substitution: The stronger response is substituted for the weaker one. When the counterconditioning procedure is successful in eliminating a reflex, it is not necessarily the case that the process responsible is simple stimulus substitution. Other possible explanations that have been proposed are conditioned inhibition, habituation, and extinction.

Two types of counterconditioning have been widely used for therapeutic purposes with humans. These procedures are distinguished chiefly by whether the goal is to increase or decrease the attractiveness of a stimulus. In appetitive counterconditioning, the desired outcome is an increase in attractiveness, as in the case of Peter and the feared rabbit. Systematic desensitization is the most widely used technique based on this type of counterconditioning. Instead of using food as the positive countering stimulus, desensitization employs muscle relaxation. The goal is to reduce a fear response to a specific stimulus.

In aversive counterconditioning, a stimulus becomes less attractive as a result of being paired with an aversive stimulus. An example is the use of electric shock paired with sexually deviant pictures to reduce sexual attraction.

Jones was not the first to appreciate the therapeutic potential of counterconditioning. In a paper describing the conditioning of a fear response in an 11-month-old child, J. B. Watson and R. Rayner (1920) suggested a procedure similar to the one used with Peter. And in a study reported after Jones's paper was published but almost certainly conducted prior to it, Ivan Pavlov (1927) treated a dog who became agitated when placed in an experimental stand by feeding him while the dog was in the apparatus. None of this early work had an impact on clinical practice, and widespread use of treatments based on counterconditioning did not occur until Joseph Wolpe developed systematic desensitization some 30 years later.

COUNTERTRANSFERENCE

Countertransference refers to feelings that arise in the therapist in response to the patient during the course of the patient's treatment. In its narrowest sense, the term *countertransference* is defined as the therapist's transferential reactions to the patient. Like all transferential reactions, countertransference involves a displacement onto the patient of feelings, beliefs, or impulses that were experienced previously by the therapist toward another person or persons.

The term *counter-transference* was first articulated by Freud to describe the therapist's affective reactions to the patient: "We have begun to consider the 'counter-transference,' which arises in the physician as a result of the patient's influence on his unconscious feelings, and have nearly come to the point of requiring the physician to recognize and overcome this counter-transference in himself" (1910/1961, pp. 144–145). Although Freud never explicitly defined the scope and nature of countertransference feelings, his work has largely been interpreted to mean that countertransference interferes with the progress of therapy. Accordingly, the neutrality required of the therapist in the therapeutic setting cannot be achieved unless countertransference feelings are contained or eliminated. This interpretation of Freudian theory conforms with the classical definition of countertransference feelings as deriving solely from the therapist's unresolved conflicts, without regard for the patient's contribution to the therapist's affective response.

The classical definition of countertransference went largely unchallenged until the middle of the twentieth century, when relational models of psychoanalytic thought began to reconceptualize the meaning of emotional experience as a reflection of self in relation to other. This shift from intrapsychic drive to interpersonal interaction was accompanied by a shift in the theory of therapy that recast the therapist in the role of "participant-observer" in the therapeutic process (Sullivan, 1953). The relational model of psychotherapy viewed the therapist's countertransference feelings as both relevant and inevitable. In contrast to classical theory, the feelings aroused in the therapist provided a critical source of information about both the patient and the therapeutic process. Furthermore, the distinction between real and distorted countertransference responses was rejected as a false one. A new definition, variously termed "totalist" or "objective" countertransference, broadened countertransference to include the therapist's total response to the patient, conscious and unconscious, real and distorted.

The role of countertransference in therapy varies depending on whether countertransference is defined from a classical or totalist perspective. According to the classical approach, countertransference derives solely from the therapist's own, unresolved conflicts and must be avoided or controlled if the therapist is to work effectively with the patient. The task of the classical therapist is to become a tabula rasa, free of subjective distortions. This means that the therapist strives to banish emotional reactions to the patient in order more effectively to attend to the patient's unconscious communications. Only by maintaining neutrality can the therapist accurately interpret the patient's transference distortions. For example, a therapist who finds the patient to be flirtatious will strive to banish from the therapist's own affective responses and actions any reciprocal response. In this way, the material remains untarnished by the therapist's countertransference reactions.

By contrast, the totalist approach includes in its definition of countertransference both "real" and distorted reactions to the patient and considers these reactions to be unavoidable. Far from impeding the interpretation of the patient's unconscious communications, the totalist view regards countertransference as a mechanism by which the patient's unconscious communications may be understood. The relational therapist, therefore, attends carefully to countertransference feelings to expand his or her awareness of the relational patterns that manifest themselves in the therapeutic setting. The therapist who becomes aware of a patient's flirtation, for example, might then use his or her awareness of the flirtation as a source of data with regard to the patient's relational experience.

The neutrality of the classical therapist removes countertransference feelings from the realm of therapeutic inquiry. Because the therapist disregards emotional reactions to the patient, the patient's experience of the therapist is necessarily transferential. In other words, the patient's primary experience of the therapist has nothing to do with the therapist's actual behavior, thoughts, or feelings, but instead reflects some aspect of the patient's past that has been transferred into the therapeutic relationship. The manifestation of countertransference feelings, if it does occur, is a mistake that must be rectified. The classical approach avoids discussion of countertransference feelings by interpreting the patient's experience of the therapist as a manifestation of transference. For example, the therapist might interpret the patient's experience of irritation on the part of the therapist to be a transferential reaction stemming from the patient's aggressive wishes.

Because the totalist view considers countertransference reactions to be an inevitable component of the therapeutic process, the patient's observations of the therapist always reflect some mixing of objective reality and transferential distortions. Rather than assuming the patient's reactions to be transferential, the therapist examines the nature of the transference-countertransference interactions to see how they reflect the patient's relational history and experience. Whereas the classical approach is to keep countertransference feelings out of the room, the totalist sees the inevitable unfolding of the transference-countertransference enactment as a potential road map to the patient's intrapsychic experience. In the example of the patient who experiences the therapist as irritated, the therapist might consider

whether the therapeutic interaction comprises an unconscious enactment of aggressive behavior. Rather than viewing the patient's experience as a reflection of transferential material, the therapist might interpret the intrapsychic function of the enactment to the patient. In this way the totalist approach steers clear of the "reality" versus "distortion" dichotomy and focuses instead on the meaning of inevitable affective exchanges in the therapeutic relationship.

How do the differences between classical and totalist approaches to countertransference manifest themselves in the current practice of psychodynamic psychotherapy? This question was addressed in a survey of attitudes toward countertransference among experienced analysts whose theoretical orientations, classical and interpersonal, were believed to correspond, respectively, with the classical and totalist approaches to countertransference (Mendelsohn, Bucci, & Chouhy, 1992). Classical analysts continued to understand countertransference as a distorted and inappropriate response to the patient, and they therefore viewed countertransference as an obstacle to the therapeutic work. Interpersonalist analysts defined countertransference as the total emotional reaction to the patient and viewed it as an important treatment tool. However, with respect to therapeutic technique, classical and interpersonalist analysts were in agreement that the analyst's emotional responses, including dreams, unconscious associations, and fantasies, should be used as sources of information about the patient's dynamics and transferences. Classical analysts differed from interpersonalist analysts in reporting both significantly less frequent use of their emotional reactions to the patient and significantly less frequent communication to the patient of their emotions and associations. Although this survey suggests that the debate between classical and totalist camps regarding the role of countertransference reflects in part a semantic difference regarding the term *countertransference,* it also demonstrates that the different understandings of countertransference conform to different uses of countertransference in current analytic practice (Mendelsohn et al., 1992).

CREATIVITY

Most Asian, African, and Native American traditions used creative imagination to enrich and enhance everyday life; original contributions were typically seen as gifts from deities or spirits, who used humans as "channels." These insights would often come in nighttime dreams or daytime visions, and they were thought to recreate divine truth rather than to innovate. In some of these societies, an individual who produced something unprecedented (such as a mask or weapon) would be hailed as a hero, but in others he or she would be censured for breaking with tradition. Even in Western societies, women's creativity often was undervalued, and women were given few opportunities to develop the skills, the education, or the life circumstances on which creative productivity depends.

The English word *creativity* is linked with the concept of origin itself (from the Latin *creare,* to make, and the ecclesiastical Latin, *creator* or Creator). Some psychologists focus on creative *products,* requiring that they be of social value or have attained some other type of consensual agreement if they are to be called creative. Others emphasize the *process* by which the products (artwork, technology, ideas, etc.) come into being. Others conceptualize creativity as the unique *achievement, ability,* and/or *attitude* of a person or a consortium. In each of these perspectives, there can be levels of accomplishment, utility, or originality, implying that some persons or groups can be more or less creative than others. The concept of *everyday creativity* directs attention to creative outcomes in office management, child rearing, home repairs, food preparation, or community service, as well as the dark side of creativity, innovative but destructive acts. Thus, from a Western standpoint, *creativity* is a term that can be used to describe the process of bringing something new into being by becoming sensitive to gaps in human knowledge, identifying these deficiencies, searching for their solutions, making guesses as to a potential solution, testing one's hypotheses, and communicating the final results. However, the creative process is imperfectly understood; these steps may be linear or overlap, may occur in a planned sequence or spontaneously, and may be intentional or largely unconscious. Finally, the term *creativity* is a social construct used to describe various outcomes in a number of domains, such as linguistic, musical, logical, spatial, kinesthetic, interpersonal, and intrapersonal (Gardner, 1993).

Attempts to measure the creative *process* have led to the development of various tests and measures of "divergent thinking" and other cognitive skills. Biographical inventories and personality measures have been devised in an attempt to identify the creative *person.* The creative *environment* has been assessed by various scales and questionnaires focusing on the classroom or the workplace, while creative *products* have been rated by a variety of scales (Runco, 1999). Some of these attempts at assessment have

been used to identify highly creative individuals in order to offer them special instruction; in the United States, entire programs—some of them statewide—have been based on pupils' test results. However, creativity measures have been criticized on the basis of content validity, construct validity, reliability, relevance to different populations, comprehensiveness, and the proclivity for their results to be influenced by situational or contextual factors. Some positive outcomes have resulted from assessing level or type of creativity through the use of such naturalistic assignments as writing a short story, assembling collages, or engaging in spontaneous problem solving. Despite their shortcomings, creativity tests have been utilized in many important research projects (Barron & Harrington, 1981).

Creative training programs assume that creative behavior can be enhanced, an assumption that has not gained acceptance among those psychologists for whom biological determinants and early learning are important variables. Some approaches admit that key creativity skills cannot be affected within a short span of time, since these components include such elements as knowledge of the topic, technical skills, and working and cognitive styles. As a result, these programs emphasize task motivation through modeling, fantasy, and a deemphasis on evaluation. Other programs take a more optimistic view, focusing on cognitive rather than social psychological methods; for example, brainstorming and creative problem solving teach people how to generate unusual ideas. Some programs for school children have been found effective in improving scores on standard creativity tests (Amabile, 1983). Several elements converge to form creativity (e.g., intelligence, accumulated knowledge, cognitive styles, personality traits, motivation, and environmental variables; Sternberg & Lubart, 1995), and training programs need to address these elements in a systematic manner.

When personality characteristics of people identified as creative are observed, a common set of characteristics usually emerges, such as broad interests, high energy levels, attraction to complexity, independence of judgment, autonomy, use of intuition, ability to resolve paradoxes or to accommodate apparently opposite or conflicting aspects of one's self-concept, and a firm sense of one's self as creative (Barron & Harrington, 1981). However, there appear to be important differences among groups of creative people: Artists have been described as more emotionally sensitive, tense, and impractical than scientists; many scientists grew up as "intellectual rebels"; musicians have suffered more problems with substance abuse, poets more mania and psychosis, and writers more bipolar disorders (Ludwig, 1995).

Future research studies need to identify the genetic markers for creative activity, reconcile personality and cognitive research data in creativity, evaluate the role played by altered states of consciousness in creative ideation, determine the part played by mental illness in blocking or facilitating creative expression, and specify what home and school variables are critical factors in creative development. The need for creative solutions to the world's many social, economic, and environmental problems reflects the importance of this field and of the psychologists who dedicate themselves to studying it.

CRITICAL INCIDENT TECHNIQUE

The critical incident technique is a job analysis method first described by John Flanagan in 1954. The method involves the collection of hundreds of anecdotal descriptions of effective and ineffective job behaviors that job incumbents, supervisors, and others have actually observed in the work setting. These anecdotes, called *critical incidents,* must be specific behaviors that exemplify success or failure in some aspect of the job being analyzed. For example, a critical ineffective incident for a truck driver would be "The driver failed to look in his rear-view mirror when backing up the truck and consequently hit a parked car." The observer reporting the critical incident is typically asked to describe (1) what led up to the incident and the context in which it occurred; (2) exactly what the individual did that was effective or ineffective; (3) the apparent consequences of this behavior; and (4) whether or not the consequences were under the individual's control.

After several hundred critical incidents are collected, they are content-analyzed and sorted by one or more judges into categories or dimensions of critical job behavior. These dimensions then serve as the basis for the identification or construction of job-related tests and other selection devices. They can also be used as a basis for the development of training programs.

In *Applied Psychology in Personnel Management,* Cascio

(1982) noted that a major advantage of the critical incident technique as a job analysis method is that it focuses on observable, measurable job behaviors. Disadvantages of the method include the considerable amount of time and effort required to implement it and its neglect of average job performance.

The critical incident technique has been employed for several purposes other than job analysis. In 1959 Herzberg and his coworkers (Herzberg, Mausner, & Snyderman, 1959) used the method to research work motivation and satisfaction. Flanagan and Burns (1955) showed how the critical incident technique could be adapted for use as a work performance appraisal and development tool. The application of Thurstone scaling to critical incidents, suggested most notably by Smith and Kendall (1963), has led to the development of several work performance appraisal techniques, including behaviorally anchored rating scales, mixed standard rating scales, and weighted checklists. In "Spin-Offs From Behavior Expectation Scale Procedures," Blood (1974) showed how critical incidents could be used to investigate organizational policy. The critical incident technique has also been used to improve workplace and product safety and efficiency.

CROSS-CULTURAL COUNSELING

Cross-cultural counseling describes any psychological helping relationships in formal or informal settings where a trained provider provides a helping human service to a culturally different client-consumer. Historically, cross-cultural counseling has adapted Western, dominant-culture methods to meet the needs of non-Western, minority clients.

Whereas the fields of psychoanalysis and anthropology were initially the focus of interest in studying cultures and mental health, the focus has since shifted from the anthropological study of remote and exotic cultures to cultural variations in modern pluralistic and complex societies. Psychology has conventionally assumed that there is a fixed or absolutist perspective of mental functioning and that culture distorts that universal definition of normal behavior. The contrasting perspective of anthropology assumed that cultural differences illuminate attitudes, values, and perspectives that differ across cultures in a relativist perspective. Cross-cultural counseling attempts to reconcile these two extreme positions.

The cultural context can be narrowly defined to include only ethnic or national aspects, but *culture* may also be broadly defined to include ethnographic and demographic status and formal or informal affiliations. Cross-cultural counseling has generally been used to describe the national and international applications of counseling across all cultural boundaries (Pedersen, Draguns, Lonner, & Trimble, 2001; Ponterotto, Casas, Suzuki & Alexander, 2002; Sue & Sue, 1999). A weakness of the *cross-cultural counseling* term is that it implies the comparison of cultures, with an implicit judgment that some cultures are better than others. In recent years the term *multicultural counseling* has been preferred over *cross-cultural counseling* to emphasize the multiplicity of equally valued cultural groups and contexts in which counseling occurs.

As non-Western countries and cultures have modernized and urbanized on a global scale, sources of traditional village, religious, and family authority and social support have been weakened, and Westernized models of counseling services have become more popular. As an alternative to the transfer of Western models, indigenous therapies are also becoming more popular. The transfer of counseling outside the Euro-American cultural context has revealed cultural biases in the conventional descriptions of counseling and therapy.

The presence of cultural bias in counseling has been well documented. Wrenn (1962) defined the "culturally encapsulated counselor" as one who had substituted symbiotic modal stereotypes for the real world, disregarded cultural variations among clients, and dogmatized technique-oriented definitions of counseling and therapy. Western-trained counselors are likely to promote the individualistic assumptions of a dominant culture intentionally or unintentionally as they transfer the dominant culture perspective of counseling to their clients.

The Basic Behavioral Science Task Force of the National Advisory Mental Health Council (1996) has identified specific examples of how social and cultural beliefs influence diagnosis and treatment, how diagnostic categories reflect majority culture values, how diagnosis differs across cultures, how symptoms are expressed differently across cultures, and the effect of most providers' being from a majority culture background while most clients come from minority cultural groups.

In the 1970s research demonstrated that mental health services were being underutilized by minority groups and that behavior described as pathological in a minority culture, such as individualistic assertiveness, may be viewed as adaptive in a majority culture client. Asian Americans, Blacks, Chicanos, American Indians, and other minority groups terminate counseling significantly earlier than Anglo clients (Sue & Sue, 1999). In most of the research literature these examples of underutilization are explained by cultural barriers that hinder the formation of good counseling relationships, language barriers, class-bound values, and culture-bound attitudes.

Cross-cultural counselors have failed to develop grounded theory based on empirical data for several reasons. First, the emphasis has been on abnormal rather than normal behavior across cultures. Second, only in the 1970s did a pancultural core emerge for the more serious categories of disturbance such as Schizophrenia and affective psychoses, so that they are recognizable according to uniform symptoms across cultures, even though tremendous cultural variations continue to exist. Third, the complexity of research on therapy across cultural lines is difficult to measure. Fourth, the research has lacked an applied emphasis related to practical concerns of program development, service delivery, and techniques of treatment. Fifth, there has been insufficient interdisciplinary collaboration across psychology, psychiatry, and anthropology, and each approaches culture and mental health from a different perspective. Sixth, the emphasis of research has been on the symptom as a basic variable, to the neglect of the interaction with the community's needs (Pedersen et al., 2002).

Culturally sensitive competencies were developed from the mid-1980s describing a three-stage developmental sequence beginning with multicultural awareness, then moving to multicultural knowledge and finally to multicultural skill competencies (Sue et al., 1982). This framework has been elaborated by Sue and colleagues (1998). These multicultural competencies have been adopted by Division 17 (Counseling) of the American Psychological Association as well as the American Counseling Association as standards for professional conduct.

The future of cross-cultural counseling will depend on advances in four areas: (1) Conceptual and theoretical approaches need to be developed (Sue, Ivey, & Pedersen, 1996); (2) a more focused research effort is needed to identify those primary variables that will explain what has happened, interpret what is happening, and perhaps predict what is going to happen in the migration of persons and ideas across cultures; (3) criteria of expertise for the education and training of professionals to work across cultures need to be defined to adequately prepare providers to deal with the problems of a pluralistic society; and (4) revolutionary modes of providing services need to be developed based on new theory, research, and training so that counseling is equitably and appropriately provided to all members of our pluralistic society.

CROSS-CULTURAL PSYCHOLOGY

Introduction and Overview

The study of human behavior must include observations made all around the world, not just in the few highly industrialized nations where most research has historically been done. The concept of culture summarizes many of the major influences on human behavior and the bases for concepts of self and group identity that people hold. Further, aspects of culture have major effects on the formulation, dissemination, and acceptance of programs designed to deliver psychological services or to use psychological principles. Cross-cultural research is also central to theory development and to programs aimed at applying the lessons learned from research (Brislin, 2000; Berry, Poortinga, & Pandey, 1997; Triandis & Suh, 2002).

Definitions of Culture

As with many complex concepts long studied by psychologists, such as personality, intelligence, and abnormal behavior, no one definition of *culture* is widely accepted. Psychologists have not spent much effort developing definitions of culture but have benefited from the efforts of their

colleagues in anthropology. Alfred Kroeber and Clyde Kluckhohn, in "Culture: A Critical Review of Concepts and Definitions," concluded by suggesting that many definitions contained "patterns, explicit and implicit, of or for behavior transmitted by symbols, constituting the distinctive achievements of human groups . . . [and] ideas and their attached values" (Kroeber & Kluckhohn, 1952, p. 181). Melville Herskovits, in *Man and His Works* (1948, p. 17), proposed the equally influential generalization that culture is "the man-made part of the human environment."

In *The Analysis of Subjective Culture,* Harry Triandis (1972) benefited from Herskovits's contribution and made a distinction between physical and subjective culture. The former would include man-made objects such as houses and tools, while the latter comprises people's responses to those objects in the form of values, roles, and attitudes. It is important to delimit the concept of culture, lest it be so all-encompassing as to explain little or nothing in particular. Violent storms are not best conceptualized as part of a culture, even though a certain society may inhabit an area in a hurricane belt. However, people's reactions to storms, in the form of preparations or collective action following a disaster, are indeed part of their culture.

Since much cross-cultural research has the goal of understanding concepts as seen by people in the culture under study, the influence of cognitive psychology has been strong. Much research has focused on people's knowledge about their world, their communication with one another given this shared knowledge, and the transmittal of this knowledge to the next generation. Given this emphasis, a third definition of culture suggested by Clifford Geertz (1973, p. 89) captures the flavor of much cross-cultural research: "Culture denotes an historically transmitted pattern of meanings embodied in symbols, a system of inherited conceptions expressed in symbolic forms by means of which men communicate, perpetuate, and develop their knowledge about and attitudes toward life."

In research programs, many psychologists use aspects of all three definitions. In studies of ethnocentrism, for instance, the fact that ideas have "attached value"—suggested by Kroeber and Kluckhohn—should be added to the concept of "symbolic forms," which Geertz formulated. The fact that people's symbols are valued leads to ethnocentric thinking, especially concerning subjective elements such as ideology, religion, morality, or law. *Ethnocentrism* refers to the deeply held belief that one's own culture is the best (defined by that culture's own standards) and that others are inferior in many ways. People almost uniformly believe that what they do is good or right and that members of other cultures are somewhat backward and/or illogical concerning their customs, rituals, food, interpersonal relationships, and other aspects of everyday behavior.

Goals of Cross-Cultural Psychology

Cross-cultural psychology is the study of culture's effects on human behavior. More formally, cross-cultural psychology is the empirical study of members of various culture groups with identifiable experiences that lead to predictable and significant similarities and differences in behavior. People's experiences take place in various social contexts, and so the study of culture often includes analysis of the social contexts in which people find themselves.

Social context has been notoriously difficult to operationalize (Markus & Kitayama, 1998). The study of social context has been an active research focus for cross-cultural psychologists (Cole & Means, 1981; Kagitcibasi, 1997). In their own culture, investigators are so close to the same social contexts as the participants in their research projects that separation of person from context is difficult. In other cultures, since visiting investigators have not had much experience with various everyday social contexts, they can more easily separate themselves from social situations and formulate hypotheses about the relative contributions of individual and contextual factors (Hall, 1977; Brislin, 2000).

At times, psychologists interested in the applications of research knowledge can take advantage of knowledge about social context. Jordan and Tharp (1979) developed programs to teach Hawaiian and part-Hawaiian children to read. They had little success after importing methods found to be effective in the United States or Western Europe. They did research, however, on children's everyday behavior in their homes and in their communities, and found that the children spent large amounts of time sitting around telling stories to one another and listening to adults tell such stories. The researchers then used knowledge of this practice, called *talk story* in Hawaii, in the classroom. They found that if children read their books as members of small groups and then discussed what they had just read, reading skills improved dramatically.

Conclusion

Any definition of psychology must take into account observations made in various parts of the world, not just those few countries in which most psychological research has historically been done. Cross-cultural studies, then, are central to the development of psychology. Cross-cultural contributions should increase in the future, as more and more psychologists in various countries free themselves from the shackles of imposed theories from Euro-American sources (Draguns, 2001). Psychologists in various countries can develop their own theories to explain research findings that differ from predictions based on Euro-American theories.

CROSS-CULTURAL RESEARCH: COMMUNICATING WITH PARTICIPANTS

Cross-cultural research methods have become a specialized study area and have been the focus of entire texts (Brislin, Lonner, & Thorndike, 1973; Triandis & Berry, 1980; Berry, Poortinga, & Pandey, 1997). A basic aspect of good methodology is communicating with subjects. Without clear understanding of instructions directed from the researcher to the participants, and without clear understanding of what responses mean, a research study not only may be misleading but may also possibly be damaging (Bhawuk, 2001).

Various techniques have been devised to ensure good communication between researchers and participants. Irvine and Carroll (1980) suggest a number of steps in testing, such as separation of individual subtests to avoid confusion; oral instructions with visual aids; translation of instructions carried out by typical members of the respondent group; supervised practice on sample items; commencement of each test session with items already familiar to respondents; and creation of an enjoyable atmosphere for testing. If the subject matter under study is a complex concept, such as the stage reached according to Piagetian theories of mental development, training studies can be introduced (Dasen, Lavallee, & Retschitzki, 1979). The acquisition of Piagetian stages is influenced by people's previous experiences; people in various cultures do not have the same everyday experiences that might lead (at least at the same rate) to the various stages. Realizing this, Dasen and his colleagues (working among the Baoule in West Africa) created training studies in which the same sorts of experiences, theoretically posited as triggering a given stage, were emulated. Compared to a control group that did not have the training experience, experimental subjects scored higher on independently assessed Piagetian tasks. Without the training study—one example of researchers' attempts to empathize with respondents, so that competencies and not just atypical performances are assessed—conclusions about "slower development" might have been made.

A little creativity may ensure researcher-participant communication. De Lacey (1970) made sure that Australian aboriginal children understood such terms as *red, circle,* and *round* by showing them wooden replicas and inviting them to handle the different shapes that were painted different colors. They were also asked to indicate examples of the terms before the actual experiment on classification ability began. In another study, Price-Williams (1961) tested the acquisition of various Piagetian concepts among the Tiv of Central Africa. In his experiment on the conservation of discontinuous qualities, the normal Piagetian method is to use beads in containers. Price-Williams tried his method but found communication difficulties were prevalent, so he changed the materials to nuts, which are far more familiar in the Tiv culture. Results showed a degree of conservation similar to acculturated European groups of children. In many cross-cultural studies of theoretical ideas where Euro-American children might be compared with children from other cultures, there is a factor that can be called *explicit attention to communication with subjects.* When this factor is clearly present in a study, there is a much greater probability of similar Euro-American and other-culture results (e.g., Dasen & Heron, 1981).

If researchers are attentive to communication issues, they will be alert to an important fact: If a person cannot perform a task or do well on a test, this does not mean there is a deficiency in ability. This implication contrasts with the normal inference that if a person does not perform well, then there is no competence or ability. The preferred interpretation, supported vigorously by Cole and Scribner (1974), is that the task itself or the situational nature of the testing situation may well be causing the poor performance. These situational elements include uncommon materials involved in the task; unfamiliar time pressures to complete the task; the presence of a nervousness-producing, high-status outsider doing the testing; and so forth. Cole has used the research technique of redesigning the testing situation until the person performs well on the task, taking the original poorer performance only as a starting point. Sometimes this is a very difficult research procedure to implement, but when successful it gives infinitely more infor-

mation about the exact reasons and exact cues for good performance than if one stops immediately after the first testing. The cues that brought out good performance, such as those that encourage effective organization of information rather than rote memorization, can then be used in other learning situations.

In cross-cultural studies, research instruments have to be prepared in languages other than the researchers' own. One of the most important recommendations in such studies is to "decenter" instruments (Brislin, 2000). Instruments should not be prepared in one language with the expectation that they be translated without modifications into other languages. Such a procedure often forces the use of stilted, unfamiliar phrases in other languages that leads to poor communication. In decentering, materials are prepared at the earliest stages so that the wordings chosen will lead to clear and familiar wordings in all the languages that are part of the research study. There is no "center" to the research (e.g., instruments from the United States that must be translated verbatim) in this recommended procedure. Researchers should work closely with translators and should ask them to identify phrases that are difficult to translate or that will lead to wordings unfamiliar to the eventual respondents in the research study.

Cross-cultural data can edit findings found in only a few countries and thus point to the specific limitations of theories. Further, cross-cultural data can provide a stimulus to new thinking, which in turn leads to new and more powerful theories. As more and more psychologists accept the necessity of taking a worldwide view of human behavior, the necessity for a special section on cross-cultural studies will vanish.

CROSS-CULTURAL TRAINING PROGRAMS

Cross-cultural training programs refer to formal efforts designed to prepare people to live and work in cultures other than their own (Bhawuk, 2001; Brislin & Yoshida, 1994; Cushner & Brislin, 1996; Landis & Bhagat, 1996; Paige, 1992). Ideally, such programs are structured, staffed by professionals with relevant training and experience, designed with an adequate budget, and conducted in a setting designed to create an atmosphere conducive to learning. The nature of cross-cultural training is made clearer when its opposite is considered. Before going overseas on a business assignment, good training can prepare people for the stresses of adjusting to another culture and differing ways of carrying out business negotiations in other cultures, and can provide advice on accomplishing one's goals. The opposite is to simply send people abroad with no preparation and to let them sink or swim on their own.

The vast majority of research and careful thinking about cross-cultural training has taken place since World War II. Reasons include the greater movement of students who take advantage of educational opportunities in countries other than their own, increases in technical assistance programs, the increased availability of jet travel, the development of global marketplaces, increases in the number of programs aimed at person-to-person contact across cultural boundaries (e.g., the Peace Corps and youth exchange programs), and increases in the number of independent countries, which necessitates greater amounts of diplomatic contact. In addition to preparing people to live in countries other than their own, cross-cultural training programs also are designed to help people work effectively with culturally different individuals within their own country. For example, programs have been designed for Anglo social workers who are about to work with refugees from Southeast Asia and for Japanese-American teachers in Hawaii who have large numbers of students of Hawaiian ancestry. People skillful in designing and implementing cross-

cultural training programs can be found in colleges and universities, the personnel departments of large businesses, government service, public school systems, churches, social welfare agencies, counseling centers, and private consulting firms.

Goals of Training

Training programs are commonly designed with four goals in mind (Brislin, 2000; Hammer, 1989, 1992). For the sake of convenience, programs to prepare people for overseas assignments will be treated here, although very similar arguments can be made about programs to increase effective intercultural contact *within* any one large country. The first goal of training programs is to prepare people to enjoy and to benefit from their overseas assignment, not simply to tolerate an unpleasant interruption in their lives. Because few people can enjoy their assignments without cordial and effective interactions with others, programs should give guidance on developing good interpersonal relations with host country nationals, both in the workplace and during voluntary leisure time. One way of measuring progress toward this goal is that people on overseas assignments should be able to list people with whom they work well, with whom they interact during their leisure time, and whom they can call on in times of need. Second, and at the same time, the host country's point of view needs to be given attention. Good training increases the probability that people in the host country will have positive attitudes about the sojourners in their country. By examining these two goals, trainers can avoid the mistake of making conclusions based on people's *reports* of positive relations with hosts. In some cases, people can make a list of friends, but those purported friends might report that the people are insensitive, ethnocentric, and condescending.

The third goal is to provide guidance on how participants in training programs can accomplish their goals. Virtually all sojourners have concrete goals in addition to enjoying and personally benefiting from their assignments. Overseas students want to obtain university degrees within a reasonable amount of time; overseas businesspeople want to enter into trade agreements; diplomats want to develop treaties acceptable to all sides in a conflict; technical assistance advisers want to construct sanitation facilities, irrigation systems, or medical centers; cross-cultural researchers want to establish collegial relations so that information can be gathered and shared; and so forth. Training can give people guidance on such topics as working through bureaucracies, negotiating with counterparts, keeping legal requirements in mind, identifying the resources needed for project completion, and so forth. Many times, training must be culturally specific, depending on the types of participants in programs. Foreign students working in the United States need to be prepared for the independence in scholarly inquiry that professors expect. American businesspeople working in Asia need to be more sensitive to the effects of their actions on the collective identity of their hosts (Hofstede, 2001; Triandis, Brislin, & Hui, 1988). Diplomats need to be aware of the long history of animosities that various ethnic groups within a country may bring to the bargaining table.

The fourth and final goal is to assist program participants to deal with the stress that overseas assignments can bring. The most commonly used term associated with such stress is *culture shock,* or the set of strong emotions that result from having the familiar structures of one's own culture taken away (Bochner, 1994). *People do not interact with each other in familiar ways! How they make decisions is a mystery! They never are clear when they try to communicate! They seem to talk about me all the time!* All of these feelings are very common, and cross-cultural trainers have adopted such stress-reduction methods as relaxation, cognitive restructuring, development and maintenance of valued leisure time activities, exercise, and the avoidance of health-threatening behaviors (e.g., increased alcohol use). Trainers frequently introduce the concept that program participants should not feel singled out for negative self-judgments. The feeling that "I am the only one" who is having difficulties adjusting to the other culture is common. If participants learn that most sojourners experience adjustment difficulties and feel the temptation to engage in negative self-thoughts, then the resulting stress is decreased.

Given increases in the same factors that lead to the need for effective intercultural communication, such as immigration, global business, the needs of international students, and the demands of various ethnic groups to be heard in the political arena, the future will undoubtedly see even more attention to cross-cultural training programs.

CROSS-CULTURE PSYCHOLOGY: CULTURE-UNIVERSAL AND CULTURE-SPECIFIC FRAMEWORKS

Emics and Etics

The jargon of cross-cultural specialists includes the terms *emics* and *etics,* which summarize an important central concept and analytical tool (Berry, 1969; Poortinga, 1997; Brislin, 2000). To best explain this concept, a problem that can be analyzed with the help of it will first be posed. Emics and etics will then be introduced in their abstract form and subsequently applied to the problem.

The problem involves drought and starvation in East Africa (Talbot, 1972). A group of European consultants recommended that development projects be established to increase water availability and grasslands for the Masai, an East African culture long involved in raising cattle. Instead of leading to healthier herds and better grazing areas, however, the development projects led to starvation for the cattle and eventually for some of the Masai. How can this be explained? The cross-cultural concepts of emics and etics are useful.

Emics and *etics* refer to the two goals of cross-cultural research. One is to document valid principles in all cultures and to establish theoretical frameworks useful in comparing human behavior in various cultures (Triandis & Suh, 2002). These frameworks have the goal of being culture general, useful in examining human behavior anywhere in the world. This is the *etic* goal—a term that comes from phonetic analysis. In linguistics, a phon*etic* system is one that documents and analyzes all meaningful sounds present in all languages and integrates them into a general framework. The other goal of cross-cultural research is to document valid principles of behavior within any one culture, with attention to what the people themselves value as important as well as what is familiar to them. These principles will be part of culture-specific frameworks, useful in examining behavior in one culture but with no claims about generality to other cultures. Such an analysis has to reject the importation and imposition of frameworks from outside a culture since, by definition, a researcher cannot gain insight into emics by using foreign tools; the tools must be indigenous (Kim & Berry, 1993). This latter type is an *emic* analysis—a term from phonemics. In linguistics, a phon*emic* analysis document sounds meaningful in a specific language.

An example from linguistics may be helpful. A phonetic system will have an initial *ng* sound, an initial *l* sound, and an initial *r* sound, since these are important in at least one of the world's languages. In addition, these sounds can be integrated into a general framework based on such concepts as activation of vocal cords and parts of the mouth used in making the sounds. An English phonemic system will have the *l* and *r* sounds, but not the initial *ng* sound, since the latter is not part of the English language. Japanese does not have the initial *l* and the initial *r* sound, since the language does not make a distinction between them (a fact that leads to ethnic jokes). English speakers thus have to put special effort into learning the initial *ng* sound—a task faced by many Peace Corps volunteers assigned to Pacific island cultures. Japanese speakers have to work hard on the *l-r* distinction, as most teachers of English as a second language will testify. The metaphor of emics and etics for cross-cultural research contains the elements referred to previously: what is present and absent, what is meaningful, what has to be given special attention since it is common in one system but not another, and what can be systematized into integrative frameworks.

Cross-cultural researchers have attempted to deal with both etics and emics in their research. A system proposed by Brislin (1976, 2000), drawing upon earlier work by Przeworski and Teune (1966, 1970), represents such an attempt. The researcher starts by examining concepts that may have cross-cultural validity but keeps in mind that not all aspects of those concepts will be the same in all cultures under study. Aspects may be different both for cultures across nations as well as for various cultures or subcultures within a country.

In discussing the effects of range development on the Masai culture of East Africa, Talbot (1972) analyzed the concept of "uses and care of cattle" from the perspective of the Masai and from the perspective of people from Europe and North America in charge of the development (Table 1). Members of both cultures have similar conceptualizations about several core connotations, and these are the proposed etics: provision of milk, fertilizer, and demands placed on humans for caring of cattle. But in addition to this etic core, there are differences that can be called the emics within each group.

The emphasis on quantity was a major problem in the range development projects. Prior to European contact, natural conditions such as droughts and fires effectively limited the size of herds, so the intelligent practice was to always have as many cattle as possible. But when water and grasslands became more common after development,

Table 1. Uses and Care of Cattle

North America, Europe Emics	Masai Emics
Cattle used for meat	Cattle not primarily used for meat
Cattle raised for sale	Cattle not generally raised for sale
Grazing over a large area	Grazing over small areas (to protect from predators)
Emphasis on quantity as much as quality	Emphasis on quality
Other signs of wealth and prestige available besides cattle	Cattle are a major sign of wealth and prestige
Experience with conservation	Always a struggle to maintain limited herds, hence no opportunity to think about conservation when large numbers of cattle are present

the Masai norm of "desirability of quantity," without a self-imposed norm of "desirability of limitations for the purpose of conservation," led to herds of unreasonable size. The cattle then overgrazed and destroyed the available range. In turn, cattle then died for lack of food, and the Masai themselves faced starvation. This case is frequently cited as an example of failure of technology (range development) due to ignorance of a human variable (norm of quantity). If people know these terms, advice for them as they move across cultures is to know culture general frameworks (the etics) but to constantly keep in mind that there will be culture-specific issues (emics) that must be understood (Cheung & Leung, 1998).

CULTURE AND DEPRESSION

Research interest in cross-cultural variations of major depression has increased over the past 25 years. Major depression is a worldwide problem and a leading cause of disability and mortality, particularly in developing regions where the pervasiveness is high (Murray & Lopez, 1997). Despite its worldwide existence, the prevalence and clinical presentation of depressive symptomatology remain heterogeneous.

Prevalence Rates

Epidemiological surveys indicate that the rate of lifetime major depression varies across countries and across ethnocultural groups within the same country. In the general population of the United States, the lifetime prevalence rate is approximately 17%; the lifetime risk for women ranges from 10 to 25% and from 5 to 12% for men. In five European countries (Finland, Ireland, Norway, Spain, and the United Kingdom) the prevalence rate is approximately 9% (Ayuso-Mateos et al., 2001). A cross-national comparison of affective disorders in community samples of nine countries (Canada, France, Italy, Korea, Lebanon, New Zealand, Puerto Rico, Taiwan, the United States, and West Germany) indicated annual prevalence rates ranging from 0.8% in Taiwan to 5.8% in Christchurch, New Zealand (Weissman et al., 1996). Lifetime rates of depression were lowest in Taiwan (1.5%) and highest in Beirut, Lebanon (19%). The low prevalence rate of depression in Taiwan remains less clear but is consistent with other reports that have found lifetime prevalence rates as low as 1.14% in Taiwan and 0.19% in China (Hwu et al., 1996). In addition, college students in Taiwan reported lower mean scores of depressive symptoms when they were compared to similar samples in Korea, the Philippines, and the United States (Crittenden, Fugita, Bae, Lamug, & Lin, 1992).

As noted, prevalence rates of depression also vary between ethnocultural groups within the same country. The United States is a good example of this phenomenon, given its multiethnic composition and high rate of immigration each year. Large epidemiological studies have revealed that prevalence rates differ between ethnocultural groups residing in the United States. For instance, African Americans tend to report lower lifetime prevalence rates of depression

than their Caucasian counterparts (Kessler et al., 1994; Zhang & Snowden, 1999); a similar trend has been demonstrated among Asian-American individuals. The prevalence rate among Latino individuals, however, is less consistent. Reports have stated that Latino (e.g. Burnam et al., 1987) individuals tend to report lower 1-year (Oquendo et al., 2001) and lifetime prevalence rates of depression when compared to Caucasian individuals; others have demonstrated that Latinos have significantly higher rates of lifetime depression than non-Latino whites (Kessler et al., 1994).

Symptom Presentation

Cultural factors can influence the expression of depressive symptomatology and often function as the lens through which we interpret and define reality. Although misdiagnosis, underdiagnosis, and overestimation of psychiatric disorders continue to be problems when patient and clinician are from different cultural backgrounds (Paniagua, 2000), they can be greatly diminished if we increase our awareness of cultural factors, particularly as they relate to the presentation of major depression.

The importance of considering the effect of cultural factors in the expression of depression is manifold. In the United States, for example, it is estimated that by the year 2050, half of the population will be composed of Latino, African American, Asian American, and Native American peoples (U.S. Bureau of the Census). The number of ethnic minorities seeking mental health services is likely to increase as well. It is important for clinicians to educate themselves about the difficulties of applying diagnostic criteria to individuals with varying cultural backgrounds.

Proper diagnosis requires a clinician's highest level of cultural understanding. Somatic complaints, such as nerves (*nervios;* Latino) and heart pain (Hopi Indians), are common manifestations of depressive experiences among these ethnocultural groups; furthermore, major depression fails to correspond to any category of illness within certain Native American cultures. The presentation of Western-derived symptomatology used to define diagnostic criteria for depression (i.e., in the *Diagnostic and Statistic Manual of Mental Disorders,* fourth edition [*DSM-IV*] and the *International Statistical Classification of Diseases and Related Health Problems,* 10th revision [*ICD-10*]) varies across different countries as well. For instance, insomnia, loss of energy, concentration difficulties, and thoughts of death or suicide were the most common symptoms of depression reported in the previously mentioned cross-national study. Appetite problems were most common in Beirut, Taiwan, and Korea; meanwhile, feelings of worthlessness and excessive guilt were less likely to be reported in Beirut, Taiwan, and Puerto Rico. Finally, among Asian countries, Korean individuals appear to be more likely to manifest their depressive experiences in somatic and psychological terms rather than with affective complaints (Crittenden et al., 1992).

Conclusion

The differences in prevalence rates and expression of major depression suggest that a person's culture functions as a factor that influences the expression and meaning of major depression. Understanding the meanings attached to concepts such as emotional distress, mind-body dualism, and intragroup categories of illness is likely to further our knowledge and understanding of major depression. Furthermore, demographic variables such as socioeconomic status, acculturation, and language use, for instance, need to be considered when we attempt to understand cultural influences attached to the meaning of major depression. Finally, the global popularity of the *DSM-IV* and *ICD-10* demands the inclusion of more cultural principles and considerations in light of their application to both U.S. ethnic minority and majority populations as well as populations around the world (Alarcón, 1995).

CULTURE AND HEALTH

Culture is both a product of human behavior and a regulator of behavior. It refers to the particular beliefs, customs, norms, and values of a set of people, usually defined by a special history, geography, and dialect or language. Almost all countries have different cultural groups, often called *ethnic groups,* within their borders. The United States and Indonesia are multicultural or multiethnic, whereas Japan is relatively monocultural.

Health is not just the absence of disease or infirmity but a state of physical, psychological, and social well-being. Health psychology is an applied discipline closely related to public health. It aims to improve human functioning, especially through better health care and prevention programs. Each culture has its own definition of health and health service. The Western industrialized countries tend to use a biomedical model for their services, emphasizing individual physical health. Developing countries, especially Asian ones, have a more collectivist, family-oriented, and holistic view of health and health service. Separation between mind and body is less distinct. Although Western ideas have penetrated deeply into many areas of the rest of the world, there remain strong influences from widespread folk beliefs about health. For instance, most Chinese believe that healthy nutrition requires a balance between hot and cold foods, and they accept and expect traditional Chinese medical practices such as herbal remedies, massage, and acupuncture. Within the United States the many ethnic subcultures vary in their willingness to accept Western medicine and in their faith in traditional healers such as Latino curanderos.

How many people around the world do share information regarding health? Obviously, in physical matters (as epidemics and organ transplants demonstrate) there is much in common, but what about psychological and sociocultural characteristics? One major debate in cross-cultural theorizing is between universalists and relativists (the etic-emic distinction). Psychologists tend to try to find categories and principles that apply to all cultures in varying amounts and intensity; anthropologists point out the unique patterns of each particular culture. Attempting to create a universal system, the World Health Organization (WHO) lately has put forth an international classification system for diseases and indicators of health. The measurable indicators cover health status, policies, social and economic factors, and primary care services. Reports from over 150 WHO member states are useful, but questions remain about the consistency of diagnoses and practices across countries and cultures. Particularly problematic are misdiagnoses because of poor cross-cultural understanding.

Some health-related practices are dramatically culture-bound, such as infanticide and malnutrition in girl children because of boy preference in several Asian countries. Mothers in West Papua do not take ferum tablets due to the fear of having large babies, since they have to deliver their babies by themselves in the hut in the back yard outside their homes. Certain mental illnesses, such as *amok* (sudden frenzy), *koro* (fear of penis constriction), and *taijin-kyofusho* (fear of being looked at) are thought to be culture-specific rather than universal. Anorexia Nervosa (self-starvation and distorted body image) is mainly confined to Western countries, but more recently it has been showing up in Asian locations.

Beliefs about causation of mental illness differ among cultures. For instance, Bedouin Arabs in Israel believe that symptoms occur because of supernatural powers, such as God's will or sorcery. The degree of acculturation is another aspect of understanding meanings in cross-cultural work. One American study showed a difference between normative beliefs of adolescents with Middle Eastern backgrounds who were born in the United States versus those who immigrated. The American-born adolescents were more accepting of aggression. On the positive end of health, that is, life satisfaction, there are strong differences between poorer and wealthier nations, with poor people valuing financial success and people from wealthier countries valuing home life and self-esteem. The research questions about health and ethnicity are numerous and intriguingly complex, especially when they overlap with economic and educational factors. Kazarian and Evans edited a cultural clinical psychology book in 1998. They propose a combination of clinical psychology and cultural psychology in theory, research, and practice to accommodate multicultural societies needs in mental health services.

One example of health and cultural issues from Indonesia is the overuse of injections not related to diagnosis. Such injections, especially with reuse of needles, increase the risk of communicable diseases such as hepatitis B and HIV. It is important to understand that Indonesians like ceremonies. From birth to death, Indonesians are accustomed to rituals. The practice of injection by a medical worker is like a ritual. The provider has to go through a certain sequence in the injection preparation and process. The patients feel the pain as the soluble preparation is inserted in their bodies. This ritual seems to give both parties satisfaction. The providers have done something, and the patients have received something directly into their bodies.

Such a ritual might seem strange to people from developed countries. They are accustomed to being informed and giving consent before medical intervention takes place, yet for people in Indonesia who are not well educated, the health service provider is the authority for the treatment. The patients do not have to know anything.

Since health is multidimensional worldwide, using only the biomedical model for explaining health issues is limiting and inadequate. Many different disciplines need to take part. Specifically, social sciences, such as anthropology, demography, economics, education, ethics, political science, psychology, and sociology, have been involved in health-related studies and policy making for decades. To accomplish communication and cooperation among so many disciplines covering many cultures and countries is not an easy task. Questions arise as to what names to use and how these different disciplines and traditions should be together. The involvement of social sciences in health is reflected in names, with specialties such as medical anthropology, medical ethics, medical geography, and medical psychology. The approach is still mostly within the given discipline. Medical psychology, for example, has applied different psychological theories, research, assessment instruments, and therapies to physical diseases. The needed approach for many projects, nonetheless, is more interdisciplinary so that social scientists and health scientists are contributing together to research teams.

CULTURE AND INTELLIGENCE

Introduction

Today, the recognition among many within the academy of the interdependence of genetic and environmental influences on human intelligence has to some degree quieted the nature-nurture controversy about the genesis of intelligence. This essay focuses on two issues: (1) the attributes of culture that have psychological relevance for understanding the meaning of intelligence and (2) the delineation of certain types of learning experiences within cultural niches as the mechanism by which intellectual potentials develop and find expression in behavior as developed intelligence.

Definition of Intelligence

There is no universal agreement concerning the definition of intelligence. One of the major reasons for this is the fact that the construct has differential meaning in different cultural groups. As Homo sapiens, we are born into the world with certain biologically constrained potentials to learn from and adapt to the environment in which we live. Although there continues to be endless debate about the nature, number, type, and level of these genetically programmed potentials, the search for consensus about these potentials is pointless, for two reasons. First, it is the culture in which we are born that invents a definition of intelligence to make sense of observed differences among its members and to define what its members believe and value as a culture. Secondly, it is the culture that gives structure, direction, and regulation to these embryonic potentials and to a large extent determines which ones will develop and become crystallized, which ones will atrophy, and which ones will remain unrealized. There are at least three attributes of psychologically salient attributes of culture that serve these socializing functions: values and beliefs, communicative conventions and courtesies, and symbolic modes of representation. A brief elaboration of each follows.

Values and Beliefs

Values and beliefs are overarching norms or principles that govern the daily lives of members of a social group and are reflected in the standards and expectations of what is considered right, desirable, or worthwhile. They are often tacitly embodied in tasks and social interactions in which children engage and therefore serve a socializing role in determining what potentials are worth developing, how, and what conditions are most conducive to their fullest possible expression.

Communicative Conventions and Courtesies

Communicative conventions and courtesies are the idiosyncratic modes of discourse that members of a social group use to communicate ideas, skills, emotions, and attitudes to each other in different situations. Capacities to learn and adapt to one's environment are developed and find expression as developed intelligence through social interactions. Consequently, individuals who engage in tasks requiring the deployment of intellectual processes must be familiar with and understand their implicit or explicit conventions and courtesies of communication.

Symbolic Modes of Representation

Symbolic modes of representation are to the media (e.g., linguistic, spatial, gestural) that members of a social group use for dealing with the tasks in various situations they encounter in their daily lives. Some tasks embody more than one symbolic modality (e.g., visual-spatialization, auditory-spatialization, or kinesthetic-auditory). How well individuals are able to develop their intellectual potentials depends, in part, on their familiarity with these culturally grounded modes of representation.

In sum, because tasks requiring intellectual engagement and behavior are so culturally grounded in the values, beliefs, communicative conventions, and symbolic modes of representation, intelligence is considered a culturally dependent construct. We turn now to a discussion of the role of learning experiences and cultural niches in the development of biologically constrained intellectual potentials.

Learning Experiences

Learning experiences are salient characteristics of intellectual tasks in which the child engages as well as the nature and quality of the social interactions in which he or she participates while doing such tasks. It is through the frequency and consistency of learning experiences over time that biologically constrained intellectual potentials are transformed into culturally dependent developed intelligence.

Apart from the values and beliefs embedded in tasks and the symbolic modes in which they are represented, there are two other features of tasks that must be considered: motivational appeal and level of cognitive complexity. Also, besides the mode of discourse used in communicating about intellectual tasks, the caliber of mediation to which the child is exposed must be noted as well.

Motivation Appeal

Motivational appeal describes the tacit power within tasks to arouse individuals' interest and attention, sustain the intensity of their effort, and ultimately direct their energies to use intellectual processes in successful completion of the intellectual task at hand.

Level of Cognitive Complexity

Level of complexity refers to the degree of difficulty of the intellectual task as reflected in the amount and type of intellectual processing as well as the knowledge demands required for successful completion.

Mediation

Mediation is an interactive clinical involvement in which an adult or capable peer teaches the child how to find and use the rules underlying an intellectual task. Using techniques such as cognitive modeling, scaffolding, and prompting with feedback and reinforcement, the adult or capable peer helps the child to transform the biologically constrained intellectual potentials into developed intelligence.

Cultural Niches

Biologically constrained intellectual potentials develop and find expression as developed intelligence within particular contexts in the environment that may be described as *cultural niches.* The term *niche* is borrowed from biology to describe the growth-fostering interactions or relationships that occur between organisms and their environments. The niche is described as cultural because the learning experiences that unfold with it are themselves culturally grounded. The home, the peer group, and the classroom may be described as cultural niches to the extent that the nature and quality of the learning experiences with them allow for the development and eventual transformation of biologically constrained potentials into fully developed intelligence.

Conclusion

This essay has made the case that intelligence is a biocultural construct. Humans are born with a set of biologically constrained intellectual potentials, but they develop and find expression as developed intelligence through particular types of learning experiences that unfold over time in various cultural niches in the environment.

CULTURE AND PSYCHOTHERAPY

Despite their widely different trappings, psychotherapeutic interventions are practiced in all regions of the world. Moreover, these efforts share certain general objectives, above all the relief of human suffering and distress (Prince, 1980). According to Draguns (1975), psychotherapy is crucially concerned with the establishment or restoration of a workable and stable balance between the person and his or her social milieu. Cultural considerations are thus relevant to all psychotherapy encounters. On the basis of this recognition, Pedersen (2002) has construed the cultural perspective as the fourth force in therapeutic psychology, on a par with psychodynamic, behavioral, and humanistic orientations.

These formulations are germane both to ethnic differences in multicultural environments and to variations among cultures that are geographically removed and culturally distinct. Observations of procedures of healers in other cultures, such as shamans in the Arctic, witch doctors in Africa, and modern therapists in Japan and elsewhere adapting indigenous techniques have been important sources of information. In North America, the documented underutilization of mental health services by major sociocultural minority groups has provided a stimulus for developing effective and culturally meaningful modes of therapy (Sue, 1977). Another practical challenge has been the influx of refugees, immigrants, and sojourners, some of them traumatized and in urgent need of workable and cul-

turally sensitive therapy. Even across interrelated Euro-American cultures, subtle yet consequential differences in responsiveness to psychotherapy have been noted. Moreover, psychotherapy has been increasingly recognized as a valuable source of data on the intertwining of personal dynamics and cultural precepts (Seeley, 1999).

Divergent expectations often obtrude from the very start. Across cultural barriers, clients often seek quick relief, in the form of direction, advice, and/or medication. Their complaints tend to focus on physical pain and distress. Western therapists, however, are trained to facilitate search for and discovery of the person's own solutions to problems of living, whereas their clients' cultural experience predisposes them to rely on their family's consensus and on the judgment of elders and other authority figures (Pfeiffer, 1995). More generally, North American helping services have been described as placing emphasis upon the individual, promoting action orientation, and focusing on the exploration of the client's unique and intrapsychic self (Katz, 1985).

Culturally sophisticated therapists favor flexibility, adaptability, and improvisation. Going beyond that, on the basis of experience with African clients in Paris Nathan (1994) has exhorted cross-cultural therapists to shed their ingrained preconceptions and embark upon psychotherapy with an open mind. Specifically, he recommends taking clients' beliefs seriously even when they appear to be in conflict with Western science and to respect traditional modes of problem solving and decision making. In British Columbia, Jilek (1982) has successfully incorporated Salish Indian healing rituals into therapy programs and has collaborated with traditional healers.

Experiencing and communicating empathy across a cultural gulf poses a major challenge. Stereotypes may interfere with the therapist's ability to feel a culturally different client's emotional state and to share his or her perspective. Enhancing the perceptiveness of therapists in training of the subjective experience of their culturally diverse clientele remains an urgent and ambitious objective in supervision, to be pursued both academically and experientially.

Most of the information on the role of culture in psychotherapy is based on clinical observation. On the basis of personal experience, Fish (1996) has offered five practical recommendations applicable in a variety of cultural contexts: (1) Focus upon goals rather than problems; (2) encourage talk about solutions rather than problems; (3) help the client see the problem as controllable and soluble; (4) find exceptions to the problem and use them as a wedge; and (5) promote expectations of change. Proceeding from several recent accounts of therapy across cultures, Draguns (2002) has cautioned against equating cultural differences with deficits and symptoms.

Still, there is no substitute for systematic research on psychotherapy in relation to culture, an enterprise that has barely begun. Hall (2002) has pointed out that empirically supported therapies have rarely been investigated in ethnocultural minority samples in the United States. Internationally, potentially relevant constructs have been proposed but as yet not empirically tested. Readiness for self-disclosure may vary across cultures (Toukmanian & Browers, 1998), and cultural variations in self-experience may be relevant to psychotherapy (Draguns, 2002). Attention has been focused upon the five cultural dimensions intensively investigated by Hofstede (2001): individualism-collectivism, power distance, uncertainty avoidance, masculinity-femininity, and long-term versus short-term time orientation. Specific hypotheses have been formulated, but not yet validated, concerning therapist preferences and client expectations in relation to these five constructs (Draguns, 2002). A promising multinational research project (Orlinsky, 1999) is focused on changes in the experience of psychotherapists during their careers. Qualitative, ethnographic methods have also been systematically applied in elucidating the role of culture in all aspects and phases of psychotherapy (Seeley, 2000). As these efforts are completed and extended, a more differentiated and specific body of knowledge will emerge on the interplay of culture and psychotherapy.

CULTURE-BOUND DISORDERS

The term *culture-bound disorders* refers to psychological disorders limited to members of distinct ethnocultural settings and traditions. Both the term and the concept are controversial and have been the topic of considerable debate, because they raise fundamental questions about the universality of psychological disorders. For some researchers, culture-bound disorders are simply variants of disorders found among Western people. For others, however, they represent disorders specific to non-Western people that cannot be classified among Western disorders.

A major part of the debate surrounds the question of cultural influences on psychopathology. Most psychiatric researchers have considered cultural variables unimportant. Thus, if culture-bound disorders exist, culture must be assigned an important role. This poses problems for biological conceptions of mental disorders.

A number of terms have been used to describe culture-bound disorders: (1) exotic psychoses, (2) atypical psychoses, (3) esoteric disorders, (4) hysterical psychoses, (5) ethnic psychoses, (6) culture-bound reactive syndromes, and (7) culture-specific disorders. All these terms reflect the confusion regarding the nature of these disorders. Should they be considered psychotic or neurotic disorders? Do they have biogenic or psychogenic origins? Are they simply variants of mental disorders found in Western cultures, or are they culturally unique patterns of disorder? The answers are complex. For culture-bound disorders, case observations have been limited in number and quality. Often the research material is strong on opinion and weak on fact. Because many investigators have not even had access to cases, there has been a frequent reliance on secondary information from poorly trained informants.

Types of Culture-Bound Disorders

More than 30 culture-bound disorders have been reported in the clinical and research literature. However, among these disorders only a handful have received substantive attention, of which this article limits the discussion to *latah, amok, susto,* and *koro.*

Latah

Latah is found primarily among populations residing in Malaysia and Indonesia. It is present in both males and females, but it is more frequent among the latter. Its two major components are a startle reaction and subsequent imitative behavior including echolalia (repeating what someone says), echopraxia (repeating what someone does), automatic obedience coprolalia (involuntary utterance of obscene words), altered consciousness, and fear. These behaviors can occur repeatedly. In most instances, the disorder is precipitated by a sudden stress.

H. B. M. Murphy, an anthropologist and transcultural psychiatrist, proposed a number of theories about the origins of *latah* and its relationship to cultural factors. He posits that certain Malaysian and Indonesian child-rearing practices predispose individuals toward hypersuggestibility, which then becomes linked to sexual functioning.

Researchers have speculated that *latah* is similar to hysterical disorders found in Southeast Asia, Siberia, and various parts of Japan. Pow Meng Yap, a transcultural psychiatrist who wrote extensively on culturebound disorders, noted that *latah* is similar to the following disorders: *miryachit, amurakh, olonism, imu, imubacco, young-dah-hte, bahtschi, yuan, mali-mali,* jumping, and Arctic hysteria. Of all culture-bound syndromes, *latah* has been the most popular subject among researchers.

Amok

According to Murphy, the term *amok* first appeared in the European literature in 1552 among accounts of Portuguese travelers to Southeast Asia who were describing religious zealots who had taken vows to sacrifice their lives in battle against the enemy. Over time, the term came to refer to individuals who emerge from periods of withdrawal and apathy with a sudden outburst of mania, agitation, and violent physical attacks on nearby people. Frequently, the attack ends when the *amok* individual is shot or killed by others in self-defense.

A number of theories of *amok* were advanced, variously attributing it to febrile diseases (e.g., malaria), nonfebrile diseases (e.g., syphilis), opium addiction, chronic disorders (e.g., brain damage), and sociopsychological distress. No theory has achieved lasting acceptance, and some re-

searchers have come to conclude that *amok* does not represent a distinct disease syndrome but rather an explosive dissociative state that can occur from a number of causes.

Pfeiffer noted that *amok* can be caused by a variety of factors, including chronic illness, infections, sleep deprivation, sexual arousal, environmental stress, or heat. He claims it proceeds through three phases. In the first phase, the individual is withdrawn, passive, and neurasthenic. In the second phase, he (virtually all victims are male) experiences depersonalization, derealization, paranoia, rage, and somatic symptoms. In the third or *amok* phase, there is sudden violent behavior, amnesia, screaming, rage, and assault with a weapon (e.g., a machete). If the *amok*-runner is not killed, this phase is followed by exhaustion and a return to normal consciousness. Kiev observed that *amok* is similar to disorders encountered in other parts of the world, including malignant anxiety in Africa, *cathard* in Polynesia, *psuedonite* in the Sahara desert, and *negi-negi* in the New Guinea highlands.

Susto

Susto—also known as *espanto*—is found among Hispanic populations in Central and South America and also among Hispanic migrants in North America. It has been discussed by Rubel and by Gobeil. Although *susto* occurs across both sexes and all age groups, it is most common among children and young women. The term *susto* is applied to a wide array of phenomena.

In general, *susto* refers to "soul loss." It begins with a strong sense of fear and is followed by weight loss, appetite loss, skin pallor, fatigue, lethargy, untidiness, and excessive thirst.

Several theories of *susto* have been proposed. Kiev suggested that *susto* is an anxiety disorder caused by unacceptable impulses that produce a reliance on projection, isolation, and displacement. In addition, he claims it provides a "sick" role that affords much secondary gain in the way of attention and affection. He states: "Susto is . . . a culturally meaningful anxiety hysteria syndrome that affords the sick the opportunity of being recognized." Gobeil contends that its occurrence in children may be due to insecurities and fears related to parental abandonment, especially under conditions of frequent mobility and migration.

Koro

Koro (sometimes known as *shook yong*) is found among Chinese populations in Southeast Asia and Hong Kong. In men, it is characterized by an intense fear that one's penis is withdrawing into the body. In women, it can be experienced as a fear that breasts are shrinking or labia are withdrawing into the body. However, it is primarily a male disorder. It has been described by Yap and by Rin, who attribute it to beliefs about the balance of yin (female) and yang (male) forces related to sexual excesses. The intense fear takes the form of panic attacks or even a fear of death. In addition, there is sometimes shame over one's action, especially if there is frequent resort to prostitutes or masturbation.

Classification of Culture-Bound Disorders

Although some researchers believe culture-bound disorders represent dysfunctions specific to the ethnocultural settings and traditions in which they occur, others believe they are variants of disorders found in the Western world. The latter group have suggested several classification systems for the culture-bound disorders.

Kiev offered the following classification system for the culture-bound disorders: (1) anxiety states: *koro, susto;* (2) phobic states: *malojo,* voodoo death; (3) depressive disorders: *hiwa-itchk, windigo* psychosis, malignant anxiety; (4) hysterical disorders: *latah;* (5) obsessional-compulsive neuroses: *shinkeishitsu,* frigophobia; (6) dissociative states: *amok, pibloktoq, hsieh ping,* spirit possession. For Kiev, the culture-bound disorders can be included among the subcategories of Western neurotic disorders.

Yap considered many culture-bound disorders to be variants of reactive psychoses. He suggested that they constitute four basic patterns of psychopathology: (1) primary fear reactions: *susto,* magical death, *latah, mali-mali, imu, miryachit, young-dah-hte,* and magical fright; (2) hypereridic rage reactions: *amok; negi-negi;* (3) culturally imposed nosophobias: *koro;* and (4) trance dissociation states: *windigo* psychosis, *hsieh ping.* These patterns then can be placed among the three major categories of psychogenic or reactive psychoses suggested by K. Schneider (1959): emotional syndromes (*koro, susto*), paranoid syndromes, and disordered consciousness syndromes (*latah, amok, negi-negi, hsieh ping, windigo*).

The role of cultural factors in the etiology, onset, manifestation, course, and outcome of psychological disorders is well established (Marsella & White, 1982; Triandis & Draguns, 1981). Thus it should not be surprising that distinct cultural settings and traditions should be associated with specific disorders. A major problem for Western psychiatry has been its inability to accommodate its assumptions and knowledge to the finding that every culture fosters and maintains distinct disorders. There are disorders that are universal, but even they cannot escape cultural influences. Thus in this respect all psychological disorders are culture-bound. This is the case for Schizophrenia and depression as much as it is for *koro, latah, amok,* and the other "culture-bound" disorders. Culture-bound disorders call our attention to the ethnocentric biases of Western psychiatry and thereby provide us with the opportunity to clarify the puzzle of all psychological disorders.

CULTURE SHOCK

The psychological and physiological impact on an individual of the process of initial adjustment to an unfamiliar culture is frequently labeled *culture shock.* In a multicultural situation, culture shock has been defined as the nonspecific state of tension causing a person to be in a state of readiness for any demand made by the new cultural environment. Kalvero Oberg (1960) invented the term *culture shock* to describe the anxiety resulting from losing one's sense of when to do what and how in a new culture. A visitor to a foreign culture experiencing culture shock discovers that familiar cues have been replaced by strange or unfamiliar cues.

Oberg (1960) mentioned six aspects of culture shock: (1) strain, resulting from the effort of psychological adaptation; (2) a sense of loss and deprivation, referring to former friends, status, profession, and possessions; (3) rejection by or of the culture; (4) confusion, referring to role, role expectations, feelings, and self-identity; (5) surprise, anxiety, disgust, or indignation regarding the cultural differences between old and new ways; and (6) feelings of impotence, as a result of the inability to cope in the new environment. Others have applied Oberg's term more widely to include culture fatigue, language shock, and role shock. More recently (Berry & Sam, 1997) *acculturative stress* has become the preferred term for culture shock "because it is closely linked to psychological models of stress as a response to environmental stressors" (p. 298).

Acculturation research describes three levels of difficulty for the individual in culture shock (Berry & Sam, 1997). The first level considers psychological changes that can be accomplished by simple behavioral shifts, culture learning, or the acquisition of social skills. The second level involves more difficult changes of behavior, which may result in psychosomatic problems that accompany acculturative stress. The third level involves psychopathology where changes in behavior exceed the individual's ability to cope.

Any new situation, such as a new job, new relationship, new lifestyle, or new residence, may involve some adjustment of role and change of identity resembling culture shock. *Culture shock* has come to mean the general condition in which any individual is forced to adjust to a new environment in which previously and culturally learned behaviors are no longer appropriate (Ward, 2001).

The problems of culture shock can be identified by at least six characteristics (Pedersen, 1995). First, familiar cues about how the person is supposed to behave are missing, or they now have different meanings. Second, values the person considered desirable may no longer be honored. Third, the disorientation of culture shock creates an emotional state of anxiety, depression, or even hostility, ranging from a mild uneasiness to the "white furies" of unreasonable and uncontrollable rage. Fourth, there is a dissatisfaction with the new ways and an idealization of the way things were back home. Fifth, recovery skills that used to work before do not seem to work any more. Sixth, there is a sense that this is a permanent condition that will never go away.

Peter Adler (1975) was among the early authors to hypothesize a sequence of stages in the culture shock experience in a five-stage process. The initial contact, or the honeymoon stage, is when the newly arrived individual experiences the curiosity and excitement of a tourist without any corresponding sense of responsibility for his or her own behavior. The second stage involves disintegration of familiar cues and overwhelms the individual with the requirements of the new culture. The individual typically experiences self-blame and a sense of personal inadequacy for difficulties encountered. The third stage reintegrates new cues with an increased ability to function in the new culture. However, the emotions associated with this third stage are typically anger, blame, and resentment toward the new culture for having caused difficulties unnecessarily. The fourth stage continues the process of reintegration toward gradual autonomy and increased ability to see both bad and good elements of the old and new cultures. The fifth stage is when the individual has achieved a bicultural identity and is able to function in both the old and the new cultures.

This sequence of stages has been referred to as a *U-curve,* an expression that describes the adjustment process as it moves from higher to lower and back to higher levels of competency. Although the research support for a U-curve adjustment process is controversial, the model continues to have heuristic value. Furnham and Bochner (1986) are critical of the U-curve for being simplistic. First, there are many dependent variables to consider in the adjustment process, such as depression, loneliness, and homesickness. Second, each individual begins culture shock at a different point in his or her adjustment and changes at a different rate.

Pedersen (1995) suggests several coping strategies for managing culture shock. First, the visitor needs to recognize that any important life transition is likely to result in stress and discomfort as a normal consequence. Second, the maintenance of personal integrity and self-esteem is an important resource for someone experiencing culture shock. Third, time must be allowed for the adjustment to take place without pressure or urgency. Fourth, recognizing the patterns of adjustment will help the visitor develop new skills and insights. Fifth, labeling the symptoms of culture shock will help the visitor interpret emotional responses to stress in adjustment. Sixth, being well-adjusted back home does not ensure an easy adjustment in a foreign culture. Seventh, although culture shock cannot be prevented, it is possible to prepare persons for transition and ease the adjustment process. In all instances the development of a support system is essential to helping the visitor cope with the adjustment process. The visitor learns important lessons from culture shock that cannot be learned in any other way, and to that extent culture shock contributes toward the long-term bicultural or multicultural adjustment of the visitor (Berry & Sam, 1997).

CURRENT PSYCHOTHERAPIES

Several popular and classical different systems of psychotherapy are outlined in this article, although for the sake of brevity some important systems and techniques are omitted.

Psychoanalytic Psychotherapy

Classical psychoanalysis was originated by Sigmund Freud in the mid-1890s and has since been modified—and often turned into analytically oriented psychotherapy by many neo-Freudians.

According to psychoanalysis, emotional disturbances and behavioral dysfunction mainly arise from (1) early childhood experiences; (2) unconscious attitudes and experiences, often deeply repressed; (3) biologically based erotic and aggressive drives that create conflicts; (4) fixations on early sexual stages of development such as oral, anal, and genital stages; and (5) defensive maneuvers and avoidances that block people from changing.

To get at the main sources of the analysands' unconscious conflicts and to undo their serious fixations, psychoanalysts use various therapeutic techniques: (1) free association; (2) dream analysis and interpretation; (3) the development of and working through of an intense transference relationship between the analyst and analysand; (4) interpretation of the analysands' unconscious feelings and conflicts; and (5) helping clients to surrender their defenses.

Adlerian Psychotherapy or Individual Psychology

Individual psychology, originated by Alfred Adler, has been followed fairly closely but has also been significantly augmented by many psychotherapists.

According to Adlerian theory, emotional disturbances are largely related to (1) feelings of inferiority; (2) individuals' striving for their own greater glory rather than for social interest; (3) hesitancy to take risks and make full commitments to life; (4) refusal to give constructive meaning to one's existence; and (5) distorted perceptions and beliefs, leading to failure of learning.

Adlerian techniques include (1) showing clients what their life goals are and how they can change their dysfunctional lifestyles; (2) confronting them with their self-defeating ideas; (3) urging clients to take constructive actions that will change their self-sabotaging life goals; (4) encouraging clients to assume responsibility for directing their lives into more positive channels; (5) helping clients achieve the courage to be imperfect; and (6) showing clients how to develop their social interests.

Analytical (Jungian) Psychotherapy

Carl G. Jung broke with Freud around 1913. He viewed libido as general psychic energy instead of sexual energy and emphasized mythological and other symbols of causation and treatment of emotional disturbance.

According to Jungian theory, emotional disturbances largely stem from (1) interference with the individual's strong instinct of individuation; (2) complexes springing from strong unconscious compulsions; (3) guiding symbolic messages from the unconscious that lead people astray; and (4) inheritable predispositions that arise from the malfunctioning of the collective unconscious.

Jungian techniques include (1) showing clients that all suffering is a loss of meaning and that archetypes can provide healing powers; (2) helping clients symbolically understand the symptoms of their neurosis; (3) emphasizing the purposive, prospective functioning of the psyche; (4) revealing to clients the creative and healing powers of the unconscious; (5) making dream interpretations, with emphasis on the symbolic meanings of the clients' dreams; and (6) encouraging experiencing rather than mere intellectual understanding and persistently encouraging clients to pay heed to and value their own inner world.

Person-Centered Therapy

Person-centered therapy was originated by Carl Rogers in the early 1940s. Although not practiced fully by many therapists today, it is incorporated in the theory and practice of a number of theorists and therapists.

According to the Rogerian view, emotional disturbance largely arises from (1) people's acquiring a negative self-concept because others do not sufficiently accept them and provide them with suitable conditions of growth; (2) people's refusing to directly and freely admit to awareness-aspects of themselves that are not consistent with their self-concepts; and (3) self-devaluation or feelings of worthlessness.

Person-centered therapeutic techniques include (1) en-

gaging in a deep, intense caring relationship with the clients; (2) consistently displaying genuineness, congruence, and empathic understanding of the clients and their problems in the course of this relationship; (3) maintaining nondirective and nonintrusive dialogue between therapist and client; and (4) helping clients to achieve unconditional positive regard for themselves, largely through their experiencing the therapist's unconditional positive regard for them.

Cognitive-Behavioral Therapy and Rational-Emotive Behavior Therapy

Modern cognitive-behavioral therapy (CBT) originated in 1955 with Albert Ellis's Rational-Emotive Behavior Therapy (REBT). Following the lead of many philosophers, ancient and modern, CBT and REBT take a constructivist view that people largely make themselves disturbed and integrate this with the behaviorist views of John D. Watson and B. F. Skinner.

According to the theories of REBT and CBT, human disturbances stem from (1) a strong tendency, both innate and acquired, for people to act both for and against their own and their social group's interest; (2) misperceptions and unrealistic observations and conclusions; (3) absolutist and irrational beliefs that unpleasant conditions must not exist, that people absolutely cannot stand them, and that people who bring about such conditions are worthless individuals; (4) people's unreasonable escalation of their strong desires into godlike demands; and (5) pronounced interactions among people's unrealistic and absolutistic thinking, their emoting, and their self-defeating behaviors.

Therapeutic techniques include (1) showing clients that unfavorable conditions by themselves do not upset them but that they consciously or unconsciously choose to upset themselves; (2) teaching clients a number of cognitive, emotive, and behavioral methods to change their dysfunctional thinking, feelings, and behaviors; (3) agreeing with clients that they do cognitive, affective, and behavioral homework; (4) applying forceful methods such as strong self-statements and shame-attacking exercises; (5) using problem solving to change adversities in people's lives; (6) applying a variety of psychoeducational techniques such as self-monitoring and gradual change of thoughts and beliefs; (7) using skill training to improve clients' abilities, interests, and achievements; and (8) employing cognitive restructuring and relaxation methods.

Behavioral Psychotherapy

Behavioral methods in psychotherapy started with applications of the learning theories of John B. Watson and B. F. Skinner and their followers. During the 1950s and 1960s clinical applications of these principles were developed.

Behavior therapy theories hold that emotional problems largely arise from (1) ineffective or maladaptive learning; (2) conditioning by others; (3) self-conditioning and self-practice of dysfunctional actions; (4) avoidance of situations that help to create anxiety; and (5) lack of skills that lead to poor performances.

Main techniques used in Behavior therapy include (1) focusing on changing clients' present behavior; (2) actively and directively teaching clients how to change their dysfunctional behaviors and how to practice more functional ones; (3) applying imaginal and in vivo systematic desensitization of anxieties and fears; (4) showing clients how to use stimulus control in the situations that cause them problems; (5) performing skill training; (6) using contingencies of reinforcements for adaptive behavior and aversive conditioning for maladaptive behaviors; and (7) teaching relaxation techniques.

Gestalt Therapy

Gestalt therapy originated with the clinical work of Fritz Perls in the 1940s.

Gestalt therapy sees emotional disturbance as largely caused by (1) a "should" attitude toward life; (2) obsession with thinking rather than feeling and doing; (3) refusing to live in the present and centering oneself in the past or future; (4) trying to reform others instead of being oneself and accepting oneself as one is; and (5) refusing to accept responsibility for one's own decisions.

Some of the main Gestalt therapy techniques include (1) helping clients to be fully aware of their feelings in the here and now; (2) showing them how to reject cognitive interpretations and explanations of their difficulties; (3) teaching breathing and body work; and (4) helping clients achieve integration.

Experiential and Humanistic Psychotherapy

Experiential, humanistic, and existential psychotherapy began with the philosophic writings of Martin Heidegger and Martin Buber and includes a variety of theories and techniques.

Experiential, humanistic, and existential therapists generally hold that emotional disturbance has these main roots: (1) refusal to take the risk of living fully and of accepting the inevitability of death; (2) inability to own one's own life and conduct and to be fairly autonomous even though living in a community or social group; (3) overconformity, leading to continual pressure to ignore one's own experience; and (4) refusing to experiment with one's desires and wishes and instead forcing oneself into a narrow mode of experiences.

Experiential, humanistic, and existential therapists use the following techniques: (1) emphasizing clients' felt senses and their inner processes of change and development; (2) helping clients to have a profound inner sense of experience; (3) using body work and physical methods of emotional release; (4) teaching risk taking, so that clients learn to change by forcing themselves to exist differently;

(5) relating caringly and fully to clients, which encourages clients to relate caringly and fully to others; and (6) helping clients achieve unconditional positive regard or full acceptance, authenticity, self-honesty, and openness.

Transactional Analysis

Transactional analysis (TA), originated by Eric Berne in the mid-1950s, originally was designed to supplement psychoanalysis.

According to TA theory, the main causes of emotional disturbance include (1) children's receiving early messages or "tapes" from their "parent" ego states that encourage them to act in their "child" ego state instead of their more sensible and productive "adult" state; (2) the innate tendency of people to make the transactions among their ego states all-important and rigid; (3) resulting stereotyped habit patterns and lack of personal autonomy; (4) lack of early stroking or loving recognition by others; and (5) the tendency to use defensive maneuvers or games to retain and reinforce early script decisions.

Transactional therapists use a variety of techniques, especially the following: (1) tracing clients' disturbed feelings back to their early decisive moments, then reeducating the clients to feel differently; (2) helping clients to achieve a balance of ego states; (3) showing clients how to reexperience decision moments and redecide important issues through self-orientation; and (4) revealing and interrupting clients' defensive maneuvers or games.

As can be seen, all these kinds of psychotherapies seem different in many respects but also overlap with each other in several other important respects. They also include several important variations, such as interpersonal relationship therapy, which was pioneered by Harry Sullivan in the 1950s, and solution-focused therapy, which was pioneered by Steven DeShazer in 1985.

In the 1970s Arnold Lazarus attempted to integrate many leading techniques of psychotherapy into his multimodal therapy, which includes several main modalities. This was followed in the 1980s by several other leading psychotherapists, like Marvin Goldfried and Paul Wachtel, who started a popular movement to integrate and interrelate many of the major theories and practices of psychotherapy.

CUTANEOUS SENSES

Cutaneous or skin senses are aspects of what is often referred to as the "sense of touch." Studies indicate that there are four different cutaneous senses: pressure (including light touch), pain, warmth, and cold. Although they are not completely understood, it is thought that other cutaneous sensations, such as tickle and itch, are varieties of the four primary cutaneous senses.

In order for an organism to receive information, specific types of nerve endings, called *sensory receptors,* respond to particular external or internal environmental stimuli. In animal organisms, the process of sensory reception transduces, or converts, the stimuli into nerve signals that are transmitted via neurons for further processing and interpretation in the central nervous system (CNS). This provides the mechanism for a living organism to perceive and/or react to stimuli. The brain interprets these signals as feelings of light touch, pressure, heat, and cold. Other responses, such as the involuntary knee-jerk reflex, may take place at lower levels in the CNS (e.g., at the spinal cord). Still other involuntary responses may be endocrine in nature.

For the cutaneous senses, certain types of sensory receptors respond to specific stimuli. These receptors are found in the tissue that underlies the skin. Some are also found with other receptors in muscles, tendons, ligaments, and joints for kinesthetic proprioception, or awareness of body position, as we move. Body balance or equilibrium, the vestibular sense, has mechanisms in the semicircular canals of the inner ear.

There are several ways to classify sensory receptors. One way is to view them in terms of the *source* of the information to which they respond. Cutaneous receptors which respond to stimuli from the external environment are *exteroceptors,* which are affected by pain, temperature, touch, and pressure. *Interoceptors* respond to changes in the internal bodily environment, while *proprioceptors* are stimulated by changes in movement, position, and tension.

Another receptor classification plan is in terms of the *information,* or stimuli, to which specific receptor types react. Using this classification, cutaneous sense *thermoreceptors* serve for heat, *nociceptors* for painful stimuli, and *mechanoreceptors* for touch and pressure. Mechanical stimuli serve to bring about reflexes such as knee jerks. Other categories include *photoreceptors,* which respond to light, and *chemoreceptors* for smell and taste.

Dermatomes

Cutaneous receptors are not evenly distributed throughout the body in the dermis, or inner layer of the skin. The nerve pathway to the brain from the cutaneous receptors is arranged in terms of areas of the skin known as *dermatomes,* which are connected with the nerves to the spinal cord.

Two-Point Threshold

Two stimulated points on the skin cannot be distinguished from a single stimulated skin point when only one receptor

or the same nerve serves the two stimulated points. The *two-point threshold* varies with the part of the body and is related to dermatome size, the largest being for the center of the back and the smallest for the tongue tip.

Local Sign

Local sign is a term that refers to the ability of an individual to localize, without looking, the portion of the body surface at which the skin has been stimulated. Scientists have not agreed as to whether or not local sign is unlearned (innate) or learned (acquired). Both innate and acquired factors may be involved.

Light Touch and Heavy Pressure

The receptors for *light touch* are believed to comprise Meissner's corpuscles, hair follicle bulbs, and some free nerve endings. *Heavy pressure* is believed to have as its receptors the Pacinian corpuscles, which appear as onionlike bulbs, each with a central nerve fiber. Changes of pressure, rather than constant application of pressure, appear to lead to receptor function that senses vibratory pressure and touch. Adaptation to pressure takes place, as may be indicated by individuals' rapid loss of awareness of the pressure of their wearing apparel. Merkel's discs, which also respond to touch, do not quickly adapt.

Pain

More remains to be learned about both reception of *pain* from the body and the site of reception of pain in the brain. Free nerve endings appear to be receptors for skin pain. Pain functions as a warning of injury to the body. Some of these receptors send impulses into the CNS to form a two-neuron spinal-level reflex arc by way of impinging upon outgoing nerve cells to muscles. This can be seen for acute pain, for example, when the hand is withdrawn from scalding water (or following a pinprick) before the brain, which takes more neural connections to reach, receives the sensation of heat. Such intense, acute stimulation is carried by quick-transmitting nerve fibers called type A delta fibers. Slow conducting fibers called type C fibers are believed to be responsible for a sense of persistent pain. Methods of study of pain include the use of radiant heat, in order to separate the stimulation of pain from stimulation of pressure receptors. A small amount of adaptation to slight skin pain has been observed.

Warm and Cold

Receptors remain to be definitively identified for *warm and cold* stimuli, despite the fact that there are distinctly separate reception spots for such stimuli. Ruffini's corpuscles and free nerve endings are believed to be receptors for heat, although they are thought also to be involved in deep, continuous pressure. The end-bulbs of Krause, also called Krause's terminal bulbs, are believed to be thermoreceptors for cold. The sensation of *hot* does not have a separate receptor but is felt when both warm and cold receptors are stimulated simultaneously. The sensation of cold that often occurs just prior to the feeling of hot to a hot stimulus is termed *paradoxical cold.* One explanation is that it represents the reception of faster transmission to the brain from the cold receptors than from the warm receptors, although both have been stimulated together. Usually, adaptation occurs to or toward the currently prevailing temperature. A change from this adapted neutral point is then felt relatively as warm or cold. Together with sensors that respond to internal bodily environmental changes, cutaneous thermoreceptors contribute to maintenance of a consistent body temperature. In response to sensed thermal changes, to help regulate body temperature, the pores of the skin may be made larger or smaller. Observable bodily responses to thermal changes include perspiring, shivering, and panting.

CYBERNETICS

The concept of cybernetics was originally adapted from biology, computers, communication theory, and mathematics and applied to human social systems. In psychology, it first was adopted by family therapists. Cybernetics and cybernetic systems have not been fully applied to personality theories. "Cybernetics is primarily concerned with understanding and managing the organization of systems" (Keeney & Thomas, 1986, p. 263). Emphasis is placed on discerning and managing specific patterns of the organization of a social system. Cybernetics is concerned with recursive feedback loops or ongoing patterns that connect within a system. The focus is on the relationships between elements within the system. "Cybernetic systems are therefore patterns of organization that maintain stability through processes of change" (Keeney & Ross, 1983, p. 51).

Cybernetic and cybernetic systems have similarities to and differences from general systems theory, viewing organisms as systems within systems (called *suprasystems;* Keeney & Thomas, 1986; Laszlo, 1980). According to a general systems theoretical view, a system is a Gestalt with the whole being more than the sum of its parts, meanwhile maintaining a balanced, homeostatic steady state (Speer, 1970). Keeney (1983) refers to general systems theory as simple cybernetics or a lower-level cybernetics.

When using a cybernetic systems perspective, it is necessary to make an epistemological shift, changing the way causality is viewed.

An Epistemological Shift

An age-old question among philosophers refers to the causes of human behavior. When using concepts of systems theory, cybernetics, and cybernetic systems, one must shift to an unusual view of causality. A linear view states that A causes B (Keeney, 1983), or one event causes another, for example, as in the stimulus-response concept. Cybernetics and systems theory, on the other hand, are based on circular views of causality, reflected by mutually feeding patterns of behavior (Keeney, 1983): A causes B and B causes A. Keeney (1983) and Keeney and Ross (1983) refer to circular causality as simple cybernetics.

Key Concepts

Cybernetic systems theory consists of several key dynamics: self-reference, feedback patterns, homeostasis, and self-autonomy.

Self-Reference

Perception can be viewed in terms of relationships, that is, self-reference, or placing the perceiver in the observation. The relationship between the observer-perceiver and perceived reality can be analyzed in terms of patterns of relationships, because the observer is always part of the context by definition.

Feedback Patterns

Any living or mechanical system is organized by patterns connecting each element within the system. These patterns are referred to as *feedback loops* (Gerson & Barsky, 1976) or recursive (ongoing circularly fed) communicative patterns of behavior. There are positive and negative feedback loops (Gerson & Barsky, 1976; Speer, 1970). Positive feedback loops initiate change by dumping new information into the system. Negative feedback loops are patterns that help maintain the system's status quo or sameness. Balance or equilibrium can be restored through the calibration of feedback loops. At the highest level of a cybernetic system, equilibrium or homeostasis is continuously maintained through the complementary relationship between patterns of positive and negative feedback loops.

Homeostasis: A Dynamic Balance

Systems maintain a continuous ongoing dynamic balance referred to as *homeostasis* (Keeney, 1983; Speer, 1970). Keeney (1983) emphasized that all living systems maintain a dynamic balance at their highest level, or else they would self-destruct and perish. According to the views postulated by early general systems theorists, change facilitates a state of disequilibrium, and then the organism returns to equilibrium. Change is encompassed by a recursive loop of stability (Keeney, 1983). Change and stability fit together like two sides of a coin; they cannot be separated. Negative and positive feedback loops also are complementary.

Self-Autonomy

The cybernetic system is self-autonomous and self-maintained at the highest level of observation (Keeney, 1983). It also is a closed system at the highest level. Self-autonomy is maintained through the processes of *morphostasis* (patterned processes of change and stability; Speer, 1970). Paradoxically, a system's structure is maintained through calibrated patterns of change and stability.

CYCLOTHYMIC DISORDER

Cyclothymic personality, or Cyclothymic Disorder, as it is called in the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV;* American Psychiatric Association, 1994), is characterized by recurrent and intermittent mood episodes in which the individual oscillates or cycles between periods of depression and hypomania, with or without normal periods in between. Cyclothymic depressions include symptoms such as sadness, anhedonia, low energy, pessimism, poor concentration, and sleep and appetite changes resembling those observed in episodes of major depression, whereas cyclothymic hypomanic periods involve symptoms such as euphoria; high energy or activity; talkativeness; high self-confidence or grandiosity; decreased sleep; and impulsive, reckless behaviors typically observed in mania. However, unlike major depression and

mania, both types of cyclothymic mood episodes are of subsyndromal intensity and duration (2–3 days on average). Cyclothymic personality can present as predominantly depressed, predominantly hypomanic, or balanced with approximately equal proportions of high and low periods (Goodwin & Jamison, 1990).

Historically, controversy surrounded the issue of whether cyclothymia is best conceptualized as a personality temperament/disorder or a subsyndromal mood disorder (Goodwin & Jamison, 1990). Indeed, cyclothymic patients are often perceived as exhibiting features of personality disorder rather than mood disorder at first clinical presentation. Family members often describe them as "moody," "high-strung," "hyperactive," and "explosive" (Akiskal, Djenderedjian, Rosenthal, & Khani, 1977). Moreover, cyclothymics exhibit social role impairment and considerable problems in interpersonal relations (Klein, Depue, & Krauss, 1986).

Kraepelin (1921) emphasized that cyclothymia is on a continuum with full-blown bipolar (manic-depressive) disorder and, indeed, may be a precursor to it. Four lines of evidence strongly support this continuum model and suggest that cyclothymia is an integral part of the bipolar disorder spectrum. First, the behavior of cyclothymics is qualitatively similar to that of patients with full-blown bipolar disorder; cyclothymia merges imperceptibly with Bipolar II (individuals who exhibit major depressive and hypomanic episodes, but not manic episodes), and sometimes Bipolar I (individuals who exhibit both major depressive and manic episodes), Disorder at the behavioral level (Akiskal et al., 1977; Akiskal, Khani, & Scott-Strauss, 1979; Depue et al., 1981). Second, equivalent rates of bipolar disorder have been reported in the first- and second-degree relatives of cyclothymic and Bipolar I patients (Akiskal et al., 1977; Depue et al., 1981; Dunner, Russek, Russek, & Fieve, 1982), and increased rates of cyclothymia are found in the offspring of Bipolar I patients (Klein, Depue, & Slater, 1985). In addition, among monozygotic twins, when one twin had manic-depression, the other, if not also manic-depressive, was frequently cyclothymic (Bertelsen, Harvald, & Hauge, 1977). These findings suggest that cyclothymia shares a common genetic diathesis with bipolar disorder. Third, cyclothymics, like Bipolar I patients, often experience an induction of hypomanic episodes when treated with tricyclic antidepressants (Akiskal et al., 1977). In turn, lithium prophylaxis leads to clinical improvement in a significant proportion of cyclothymics, as it does in bipolar patients (Akiskal et al., 1979). Finally, up to 80% of bipolar patients exhibit cyclothymic premorbid personalities (Goodwin & Jamison, 1990; Waters, 1979). Moreover, cyclothymics are at increased risk for developing full-blown bipolar disorder. Among cyclothymics followed from 1 to 3 years, 35–40% have developed Bipolar II or I Disorder (Abramson, Alloy, Donovan, Hogan, & Whitehouse, 2003; Akiskal et al., 1977).

The onset of cyclothymia usually occurs in mid-adolescence (mean age 14 years; Akiskal et al., 1977, 1979), whereas the onset of full-blown Bipolar I or II Disorder occurs around 24 years on average (Goodwin & Jamison, 1990). Thus, there is approximately a 10-year risk period in which cyclothymics could be identified prior to the onset of full-blown bipolar disorder. Depue and colleagues (1981; Depue, Krauss, Spoont, & Arbisi, 1989) have developed the General Behavior Inventory (GBI) as a first-stage screening instrument for this purpose. The GBI has been found to identify cyclothymics in the general population reliably and validly, with high sensitivity and specificity.

Cyclothymia often presents a problem in differential diagnosis (Goodwin & Jamison, 1990). Symptoms such as hyperactivity and distractability that are part of cyclothymic hypomanic periods are easily confused with Attention-Deficit/Hyperactivity Disorder (ADHD). The key difference is that when these symptoms are part of cyclothymia, they are more episodic and more characterized by rapid swings in attention and activity level than when they are part of ADHD. The impulsive, reckless behaviors (e.g., shoplifting, substance abuse, hostility) seen in cyclothymic hypomanic periods can also be mistaken for Antisocial Personality Disorder. Here, the association of these behaviors with elevated or irritable mood states is central to the differential diagnosis.

Several personality characteristics and cognitive styles have been associated with cyclothymia. Among the offspring of bipolar patients, obsessional personality traits correlated with the presence of cyclothymia (Klein & Depue, 1985). An association between genetic liability for bipolar disorder and creativity has also been reported (Jamison, 1993), with an increased propensity for creativity being most strongly expressed in individuals with subsyndromal manifestations of the bipolar spectrum (i.e., cyclothymia; Andreason, 1987; Richards, Kinney, Lunde, Benet, & Merzel, 1988; Shapiro & Weissberg, 1999). Recent evidence indicates that cyclothymic individuals exhibit stable negative cognitive styles similar to those observed among unipolar depressed people (Alloy, Abramson, Donovan, Whitehouse, & Hogan, 2001; Alloy, Reilly-Harrington, Fresco, Whitehouse, & Zechmeister, 1999). Alloy and colleagues (1999) reported that cyclothymic individuals exhibited dysfunctional attitudes and attributional styles (styles for explaining the causes of positive and negative life events) as negative as those of dysthymic individuals and that cyclothymics' dysfunctional attitudes and attributional styles remained stable across large changes in mood and symptomatology over time.

Recent evidence suggests that the extreme mood swings observed among cyclothymic and other bipolar individuals may be attributable to both a behavioral and a biological hypersensitivity to stress. Alloy and colleagues (1999) and Reilly-Harrington, Alloy, Fresco, and Whitehouse (1999) found that cyclothymic and bipolar individuals' dysfunctional attitudes and negative attributional styles interacted with stressful life events to predict longitudinally depressive and hypomanic mood swings. Specifically, cy-

clothymic and bipolar participants with negative cognitive styles were the most likely to experience depressive and hypomanic mood swings in response to stressful events. Similarly, Depue and colleagues (Depue, Kleiman, Davis, Hutchinson, & Krauss, 1985; Goplerud & Depue, 1985) found that cyclothymics showed slower behavioral recovery following a stressful life event and slower recovery of cortisol secretion following a laboratory stressor than did normal controls.

DAYDREAMING

Daydreaming has been defined as "a dream indulged in while awake, esp. one of happiness or gratified hope or ambition; a reverie, castle in the air" (*Oxford English Dictionary*) or "a visionary fancy indulged in while awake" (*Webster's Dictionary*). Obviously, daydreaming is not a very precisely defined or discrete entity. Daydreaming can be thought of as including a number of other terms in daily parlance, such as reverie, fantasy, imagination, playful thinking, wandering thoughts, and free association.

Taken in its broadest sense, including all the aforementioned terms, daydreaming clearly occupies a great deal of our time. A long-term study of daydreaming, using a variety of questionnaire techniques, suggests that we probably spend at least half of our waking lives in daydreaming activity, and even when we are engaged in an intense waking mental task, we still spend at least 10% of the time daydreaming.

Daydreaming may be especially important in terms of our scientific study of the brain and mind because it can be thought of as the background activity of the waking mind. Daydreaming is what the mind (and the underlying brain) does naturally when it is not paying attention—when it is not constrained into performing one of the specific tasks our brains have been trained to do.

Daydreaming has been studied by a number of different techniques, most often using a variety of questionnaires asking what people daydream about and when. There have also been a series of studies designed to "catch" daydream content by having subjects wear a device which buzzes or signals them at random intervals as a signal to write down or dictate whatever was going through their minds.

More recently, there have also been studies of brain activity dealing with types of mental activity (see Brain Imaging, elsewhere in this volume). These studies are most advanced relating to rapid eye movement (REM) sleep, which is when most dreaming occurs. Daydreaming per se has not yet been clearly demonstrated to involve particular brain regions or systems, but work is in progress in that direction. Over many years, there have been studies of peripheral physiology—such measures as pulse, blood pressure, skin resistance. All of these show that emotionally arousing material produces clear-cut changes in physiological measures. These can differentiate highly emotional or charged daydreams from bland daydreams, but do not identify daydreams as such.

Overall these studies have produced many suggestive findings on daydreams. First, as previously mentioned, a large amount of total time is spent daydreaming. On the other hand, studies attempting to examine an individual daydream, insofar as it can be delineated, find that it is surprisingly short—usually 5–14 seconds in length. Studies on the content of daydreams invariably show that they are influenced by emotional concerns. We daydream especially of current concerns and, to a lesser degree, of past concerns. The more emotionally important a concern is, the more likely we are to daydream about it at the time.

A number of distinct daydreaming styles have been identified in daydreaming research. One classification divides people into (1) basically happy daydreamers, (2) unpleasant or anxious daydreamers, whose daydreams include a lot of guilt, depression and fear of failure, and (3) erratic or distractible daydreamers, whose daydreams are unfettered, ranging rapidly over many areas. Not surprisingly, the studies tend to show that daydreaming styles are related closely to results on personality tests of many kinds so that persons who are "happy daydreamers" tend to be people who score "happy" on various tests.

Can daydreams be distinguished from dreams? The very word, daydream, suggests that we all see some sort of connection. A daydream is a dream we have while awake. In fact, this is a very important question, because although we started off above thinking of daydreams as something occurring in the waking mind or as the most unconstrained state possible during waking, it may be that what happens during waking is not so different from what happens during sleep.

I was personally struck by this in one of my previous studies of nightmares. In a series of long interviews with people who had a great many nightmares at night, I realized that a number of them also talked about "daymares"—daydreams that developed in a frightening direction, went out of the subject's control, and became increasingly frightening until the subject "woke up" or snapped out of it. This made me realize that conscious control, which we often use to distinguish our waking life from our dreaming life, is not an absolute, and at least for some people daydreams take on lives of their own and are, at least temporarily, out of the dreamer's control.

Along these lines, it can be useful to think of all mental activity along a continuum, from focused waking activity at one end to dreaming at the other. The continuum would run from focused waking activity, such as doing an arithmetic problem or figuring out where to run to catch a frisbee, to the somewhat looser thinking that characterizes much of our lives, then to clear-cut daydreaming or reverie, and finally to dreaming at the other end. This continuum has a number of strands. In terms of material dealt with, focused waking activity deals with perceptional material and with imposed tasks. As we go further toward dreaming, these drop out and the material dealt with is chiefly memory. In terms of style or content, the focused waking end, at least for many people, involves simple perception or thought without definite evoked imagery (though some people are never without imagery). Then moving along the continuum imagery (especially visual imagery) becomes more and more prominent. In terms of how material is handled, we can think of the left hand end as a serial processing, moving from A to B to C to D in a straight line, whereas the right hand end involves more parallel processing. For those who think in terms of connectionist nets, on the left end of the continuum the mind acts as a "feed-forward net," and toward the right end, more of an "auto-associative net." The role of emotion, too, is important. Our emotions always influence our lives, but they have least influence on our focused waking thoughts, and an increasing influence as we move toward daydreams and dreams.

Among the studies that support the continuum point of view is a study showing that the longer subjects spend in a state of quiet relaxed sensory isolation (usually a dimly lit room or something that imposes a grey field over their vision), the more dreamlike their mental activity becomes, so that when people are in such situations for 15–30 minutes or more, what they report experiencing is very like a dream.

We recently performed a study in which students simply wrote down the most recent dream and the most recent daydream they could remember. The dreams and daydreams were then scored on a number of well-known scales by scorers blind as to condition. It was found that there was considerable overlap in the sense that the daydreams of some students were just as "dreamlike" and "bizarre" as the night dreams of other students, or more so, and this was in fact related to the personality of the student. When the students were divided into those with "thick boundaries" (solid, definite, keeping everything separate, thinking in black and white) and those with "thin boundaries" (allowing more merging, looseness, thinking in shades of grey), it turned out that both the dreams and daydreams of those with thin boundaries were considerably more dreamlike and bizarre than those with thick boundaries, and overall the daydreams of students with thin boundaries were scored on the average just as dreamlike and bizarre as the night dreams of students with thick boundaries.

Thus, in terms of our continuum from focused waking at one end to daydreaming and finally dreaming at the other end, we note that some people naturally function more at one end, and some more at the other. This may be important in overall studies of mental functioning, since it recently has become clear that night dreams do not always occur during REM sleep. REM sleep is the ideal place to find typical night dreams. Such dreams are sometimes reported from non-REM sleep, quite often from sleep onset, and from special conditions such as always preceding epileptic seizures. Neuropsychological studies suggest that there are certain areas in the cortex and other portions of the forebrain that are necessary for dreaming to occur and that REM sleep is just one way—certainly the most common way—to activate these forebrain regions. This may be relevant to daydreaming since, among the large numbers of patients studied who have brain lesions producing cessation of dreaming, most also note a cessation or paucity of daydreaming. These studies strongly suggest that daydreaming will probably turn out to involve activation of the same regions in the forebrain or very similar regions as those activated in dreaming.

I hope the above discussion makes it clear that daydreaming is part of our normal mental activities. There is nothing pathological about daydreaming per se. Nevertheless, excessive daydreaming—very hard to define—is sometimes considered a symptom of disorders such as Attention-Deficit/Hyperactivity Disorder (ADHD) and other conditions. I suggest that the problem is not daydreaming itself, but rather the deficit in attention mechanisms.

Finally, we can ask briefly whether daydreaming has a function. We cannot provide a definite answer, of course, since at this point we do not know with any certainty the functions of dreaming or even of sleep. However, it seems clear that something we spend as much time doing as daydreaming probably has some adaptive use. Thinking phylogenetically, the function may have been simply the increased success in food gathering, hunting, and so on in someone who is able to imagine possible results and to foresee possible futures. More generally, daydreaming or imagination, in the sense of developing new ideas or new possibilities, is obviously useful for the preservation of the species. In this sense, daydreaming clearly plays a part in creativity, and creativity has adaptive uses.

DEAFNESS AND HEARING LOSS

Estimates of the prevalence of hearing loss vary widely within and across countries. As one indicator, 23 million Americans (almost 10% of the population) have significant, chronic hearing losses, and 1.5 million are deaf in both ears.

Variation in the degree of hearing loss, age of hearing loss onset, and the etiologies of the losses influence the way and extent to which deafness affects psychological functioning.

Hearing losses are categorized as *conductive,* involving the middle ear; *sensorineural,* involving the inner ear and auditory nerve; or *central,* involving auditory centers of the brain. Speech perception (which directly relates to ability to interact with others, learn a spoken language, and succeed in school) is most affected by losses at frequencies 500 hertz (Hz), 1,000 Hz, and 2,000 Hz. Etiologies of hearing loss range from hereditary losses to adventitious losses that are associated with birth complications, illness, and accidents. Adventitious losses may be accompanied by damage to other sensory systems or related neurological effects. Statistics concerning the academic success of deaf children, literacy rates, intelligence, and so on thus are based on heterogeneous samples and do not purely reflect consequences of deafness. Similarly, lack of early language exposure, social interaction, and experiential diversity can affect development, but studies involving deaf children of deaf parents reveal them to be indirect effects and not a function of hearing loss per se.

The terms *deaf* and *hard of hearing* refer not only to quantitative descriptions of hearing loss but also to cultural identity. Audiologically, hearing losses from 26 to 40 decibels (dB) in the better ear are categorized as *mild,* those from 41 to 55 dB as *moderate,* from 56 to 70 dB as *moderately severe,* from 71 to 90 dB as *severe,* and losses greater than 90 dB in the better ear are categorized as *profound.* Whatever the quantitative loss, individuals may consider themselves members of the Deaf community, depending on the degree to which they identify with members and institutions in that community and whether they prefer to use signed or spoken language. Most countries have such communities, although their visibility varies.

Over 95% of deaf children have hearing parents, a situation that significantly influences language, social, and cognitive development. Deaf children of deaf parents reach developmental milestones at rates similar to hearing peers. They also exhibit the same patterns of language acquisition (e.g., errors such as overgeneralizations and pronoun reversals) as hearing children of hearing-parents peers and even have some advantages (e.g., in vocabulary size, through the one-word stage). Many deaf children of hearing parents, in contrast, show delays in various domains, particularly language and literacy. Developing a sense of identity and self-esteem may be especially challenging as many deaf children do not have exposure to deaf peers or deaf adults.

Hearing mothers tend toward overcontrol of their deaf children, but patterns of mother-child attachment generally are similar in deaf and hearing dyads. The quality of hearing parent–deaf child interactions is strongly related to effective communication, often accomplished through sign language. Natural sign languages such as American Sign Language (ASL), British Sign Language (BSL), or Italian Sign Language (LIS) are as difficult for parents to learn as any foreign language, but for children with greater hearing losses, they generally are more successful than either spoken language or the various forms of signing based on the vernacular (e.g., Signed English, Signed Mandarin).

Through the early twentieth century, psychologists believed that severe hearing loss predisposed individuals to psychopathology and intellectual inferiority. In fact, distributions in both mental health and intellectual domains are largely comparable for deaf and hearing populations. While some reports suggest that the prevalence and severity of mental illness among deaf people are greater than in the general population, that situation appears largely due to the lack of mental health services for deaf individuals and poor communication between health personnel and deaf clients. Recent studies suggest that less than 2% of deaf individuals who need mental health treatment receive it, a problem particularly acute for deaf individuals from ethnic minorities. Deaf children are still often misdiagnosed as mentally retarded due to communication barriers.

Contrary to assumptions about *sensory compensation,* hearing loss generally does not result in superior visual processing abilities. Among deaf children and adults who use natural sign languages, however, significant visual processing advantages are seen in domains such as mental rotation, face recognition, visual attention, and image generation. These differences appear to be direct results of various aspects of sign language use (i.e., deaf people who use spoken language do not exhibit them). There is also a more general enhanced sensitivity to visual signals in the periphery—evidenced in both behavioral and neurological assessments—a result of reliance on visual rather than auditory stimuli in the environment.

Early research indicated that deaf people had shorter memory spans than hearing people, a result that reinforced assumptions about intellectual deficiency. Recent research has revealed those results to result not from underlying capacity differences, but to the fact that signs consume more space in the limited-capacity working memory system (the phonological loop) relative to spoken words, a finding with parallels across spoken languages that vary in their pronunciation times for digits and words. Still, deaf individuals tend to remember less than hearing individuals in a variety of memory paradigms. In part, such results reflect more heterogeneous and less well-interconnected conceptual information in semantic memory on the part of deaf individuals, despite considerable overlap in the organizational structure of their knowledge. Deaf adults and children are also less likely to apply conceptual knowledge in various tasks, due to either their educational histories (and lower expectations of parents and teachers) or to differences in their strategic approaches to problem solving. Tasks that require relational processing or the simultaneous consideration of multiple dimensions of a stimulus appear particularly problematic, a result that has general implications for learning and psychological functioning.

Deaf children's educational success depends on early language exposure and effective communication with parents. Early exposure to sign language appears to lead to linguistic and cognitive advantages, but acquisition of literacy skills remains a significant challenge to deaf individuals. Many deaf people acquire mental representations functionally equivalent to the phonological codes that underlie reading in hearing individuals, and literacy subskills such as spelling often approach hearing norms. Nevertheless, vocabulary, grammar, and other components of reading and writing in the vernacular remain difficult for deaf children to acquire, even when they are skilled in sign language. Thus far, neither the provision of vernacular-based sign systems nor bilingual programs that involve both spoken and sign language have proven effective in significantly enhancing literacy rates among deaf individuals, and the median reading level for deaf 18-year-olds in the United States remains comparable to that of hearing 9-year-olds.

DEATH, LOSS, AND TRAUMA

Major Loss as a Unifying Construct

This article will provide a brief survey of the fields of work on death, loss, and trauma. The field of death and dying focuses almost exclusively on the dying process and various aspects of death. The field of loss and trauma is broader, encompassing both death and various types of major loss events, including dissolution of close relationships, loss of health, loss of possessions, violation of self as in rape, and losses occurring in traumatic events. Traumatic events are those that inflict major loss, frequently involving violence and multiple deaths.

The idea of experiencing a major loss is common to these literatures and integrates a variety of death and loss and trauma concepts and findings. A major loss may be defined as a reduction in resources in which the person is emotionally invested. As an example of this synthesis, bereavement and adaptation often are conceived as involving steps common to death and other forms of major loss. Such steps include emotional and cognitive processing of the event and its implications and development of an understanding of the event. This understanding may involve an account of the nature of the losses, why the event happened, and perceived consequences. Adaptation usually occurs when people are able to express their feelings about the loss, as by talking or writing about it. An important part of the adaptive process may be finding a confidant who will listen and be there as the individual tells her or his story of loss.

Death and Grief

Death and major loss in general usually result in the process of bereavement or grieving. *Grief* is defined as a person's emotional reaction to the event of loss, and as a process of realization, of making real inside the self an event that has already occurred in reality outside. The *Diagnostic and Statistical Manual of Mental Disorders* (4th ed.) of the American Psychiatric Association defines bereavement as a psychiatric disorder if it includes symptoms characteristic of "a major depressive episode . . . such as insomnia, poor appetite, and weight loss . . ." that last at least 2 months after the loss. As C. S. Lewis suggested in his 1961 book *A Grief Observed,* grief is a type of experience that most people anticipate with dread. Lewis himself died within two years of the death of his wife Joy, and it is believed that Lewis's profound grief hastened his death. In principle, however, grief is an adaptive reaction and essential to recovery. Scholars have argued that grief instinctively occurs and is focused on resolution and adaptation. When the degree of intense grieving is quite prolonged and interferes with normal functioning, the grieving person is conceived to be experiencing chronic grief.

As many scholars have noted, different types of loss and resulting grief directly affect the length and depth of the grieving experience. A distinction between *high-grief* deaths versus *low-grief* deaths often is made. A high-grief death is characterized by intense emotional and physical reactions to loss. A low-grief death is less affecting emotionally, and the bereaved is able to cope more readily. The death of a child would be the classic high-grief death. The death of a person who had reached a quite advanced age and who had lived a long and fulfilling life would be a low-grief death.

One view of grief is that it can be the prelude to positive developments in a survivor's life. In C. S. Lewis's book on grief, he wrote, "Still, there are enormous gains" (p. 49). It has been recognized that a key activity of grieving is a search for meaning that leads to insights, glimmers of understanding, and the learning of principles that help us clarify our philosophy of living and provide a more mature view of oneself and other people.

Adaptation may differ according to type of major loss. Death of a loved one is irrevocable. Nonetheless, the grieving person may continue to feel guilt, anger, and a sense of unfinished business in adapting to the loss. Loss of close relationships, as in divorce, may also elicit these responses. However, there is the possibility that the grieving person may continue to interact with the lost other, thus providing an opportunity to work on emotions such as guilt and anger. Some types of loss, including those associated with aging

and prejudice, may be subtle, leading to a feeling of disenfranchised grief. The loss connected with this type of grief is not appreciated very well by others, and there may be little support available to the individual experiencing such grief.

Trauma

Trauma is a specific term referring to unusual psychological and physiological reactions to major losses, such as the death of close others. Traumatic reactions may be so severe as to constitute Posttraumatic Stress Disorder (PTSD), which is a particular diagnostic category in psychology and psychiatry. The field that now is called traumatology began with an ancient Egyptian physician's reports of hysterical reactions that were published in 1900 B.C. in *Kunyus Papyrus* (quoted in Figley, 1993, p. 3) and that became one of the first medical texts. Traumatology may be defined as the investigation and application of knowledge about the immediate and long-term psychosocial consequences of highly stressful events and the factors that affect those consequences. This field evolved mainly within the last 2 decades, with foci both on research and therapy and application. The onslaught of studies of PTSD after the Vietnam War was a major factor in contributing to development and refinements of this field.

Conclusion

Major loss is a broad construct that helps connect the findings and ideas of literatures on different types of loss (including divorce), death, and trauma. Death and dying and traumatology are large, growing fields. With events such as the terrorism of September 11, 2001, dominating public attention in the early twenty-first century, these fields are likely to grow and become even more prominent in years to come.

DECEPTION

Deception refers to inducing a false belief in another. Although it is often successful and rewarded when undetected, targets are often subject to the influences of deception even when they know the message may be faked. False praise and adoration, as well as concealment of dislike and loathing, allow smooth interaction with others—a social lubricant. Many who distort do not consider themselves to be faking. The remainder of this paper concerns deliberate deception and its attempted measurement by psychologists in clinical and forensic contexts.

Deception can occur anywhere within the context of the psychological evaluation. The two temporal foci of distortion are the times of the evaluation and of a previous relevant event. This means that deception for the present (i.e., the time of the evaluation) may be quite different from that presented for the past (e.g., clinical, criminal, or civil event). Patients sometimes deceive to get into treatment and deny psychopathology in order to leave it. Criminal defendants may fake insanity to avoid prison and minimize deficiencies to obtain release into the community.

Simple response styles are used occasionally by the faker, for example, denying or fabricating everything possible. Usually, however, mixed response styles are used, whereby people lie selectively in different ways about different things. An individual will sometimes change styles within one evaluation session, for example, from denying problems to honest responding as fatigue increases. This makes the assessment of deception more difficult, but not impossible, for the rigorous evaluator.

Evaluation for Deception

The purposes of a deception analysis within a psychological evaluation are as follows:

1. To examine the reliability and validity of database information
2. To detect the possible existence of misrepresentation
3. To determine the response style(s) utilized by the evaluatee
4. To determine the magnitude of deception
5. To place symptoms, behaviors, or mental conditions associated with deception into clear perspective
6. To generate hypotheses for further evaluation/investigation
7. To communicate the decision path and the findings to the referral source
8. To eventually standardize the deception analysis process

In the clinical area, applications include assessment of (1) who to select for treatment, (2) readiness for discharge, (3) treatment motivation, (4) transference and countertransference, and (5) honesty of collaterals. In forensic applications, there is a wide relevance. Within the criminal area, these include (1) identification of perpetrators, (2) competency to proceed, (3) criminal responsibility, (4) violence prediction, and (5) community monitoring of treatment after release. In the civil area, applications include evalua-

tion for: (1) competency, (2) witness credibility, (3) child custody and divorce actions, (4) personal injury and wrongful death, and (5) employment screening and dishonesty.

Professional Misconceptions Regarding Deception

Throughout the history of the mental health-law disciplines, misbeliefs about deception include the following:

Most spoken words and behavior can be taken literally. Many mental-health professionals believe that deception does not occur in their evaluations. The frequency of deception in clinical settings and situations is unknown, but assumed to be high. In forensic settings, Malingering has been confirmed or suspected in more than 20% of criminal defendants, with another 5% showing substantial unintentional distortion. The deception rates for litigants in civil actions may be even higher.

The evaluator cannot be fooled (other people can). In general, mental-health professionals are not good at detecting faking. Worse yet, an inverse relationship is suggested: The greater the confidence, the lower the accuracy in detecting faking.

Deception, when it does occur, means that the faker is mentally sick. Desperate people often resort to desperate measures to survive or adapt. A person who fakes insanity is not necessarily mentally ill, but may want to avoid prison, an aversive stimulus environment under the best of conditions.

The current DSM *allows for deception analysis.* The last three *DSM*s state that Malingering should be suspected if (1) there is a forensic context to the evaluation, (2) a discrepancy between reported disability and objective findings exists, (3) there is lack of cooperation, or (4) the patient has an Antisocial Personality Disorder.

These criteria for detecting malingering are too limited, failing to take into account different styles of deception (of which Malingering is only one), extant methods of detection, and other population groups who fake. An explicit disclaimer to the use of the mental diagnoses in forensic contexts is presented in the *DSM*.

Some conditions, such as Amnesia, hallucinations, and posttrauma reactions, are easily faked and nearly impossible to prove. Faked Amnesia has been detected with promising degrees of accuracy, hovering at about 75%–85% accuracy. Other conditions can be scrutinized for deception. Claimed hallucinations are hard to disprove, yet base rates for comparison and decision criteria are available to assist the evaluator. Posttraumatic Stress Disorder (PTSD) can be assessed by psychometrics or arousal methods with built-in features to assess deception.

Detecting faking is an art and cannot be taught. The reverse appears to be true. Following a few simple rules increases the accuracy rate substantially above chance. Deception analysis is a trainable skill. The average mental health professional of any culture can be taught to adequately detect faking in a relatively short period of time.

Near absolute accuracy of detecting faking can never be achieved. It is a dangerous untruth to believe that near absolute accuracy of detecting faking can never be achieved. Recent technologies, such as DNA fingerprinting and P300 wave analysis, are nearly 100% accurate. The latter method is based on brain waves associated with stimulus familiarity rather than arousal, in contrast to methods with lower accuracy such as polygraphy, voice stress analysis, and penile plethysmography.

Psychologists face a moral dilemma much like those in the physical sciences in their development of harmful technologies. There appears to be an increased acceptance of deception as a means of exploiting others on the parts of both institutions and individuals. This issue of "too little" versus "too much" accuracy in detecting deception suggests a balancing of ethics versus efficacy. Whether the resolution of moral issues outweighs the benefits of continued technological improvements in deception analysis is a value judgment regarding the rights of the target individuals versus the needs and security issues of the larger community.

DECLARATIVE MEMORY

Declarative memory involves representations of facts and events that are subject to conscious recollection, verbal reflection, and explicit expression. Sometimes also called explicit memory, declarative memory is contrasted with procedural, implicit, or (simply) nondeclarative memory. The distinguishing features of declarative memory involve a combination of two major features. One of these features is its mode of expression, which is characterized by the ability to bring facts and experiences to mind, that is, the ability to consciously recall items in memory. The second feature involves the ability to express a recalled memory in a variety of ways, most prominently by verbal reflection on a learned fact or past experience, but also by using the memory to answer a variety of questions or solve any of a variety of problems. By contrast, nondeclarative memory is characterized by its inaccessibility to conscious recall and by expression only through implicit measures of performance, typically increases in the speed or shift in choice bias during repetition of a mental procedure (Eichenbaum & Cohen, 2001). Although several dichotomies of human memory have been proposed, most are consensual in these properties that distinguish a conscious, declarative memory from forms of unconscious memory. Finally, declarative memory is sometimes divided into two subtypes—episodic memory for specific autobiographical experiences and semantic memory for general world knowledge.

Conscious and explicit memory can be dissociated from other types of memory expression in normal human subjects (Richardson-Klavehn & Bjork, 1988; Metcalfe, Mencl, & Cottrell, 1994; Schacter, 1987) and in amnesia (e.g., Corkin, 1984; Butters & Delis, 1995; Squire, Knowlton, & Musen, 1993), leading several investigators to propose that declarative memory is a distinct form of memory. Studies on normal subjects have shown that manipulation of memory testing demands can differentially affect performance on declarative and nondeclarative memory. For example, study instructions that emphasize semantic processing over superficial phonemic processing of verbal material differentially improve success in declarative but not in nondeclarative memory, even for the same materials. In addition, manipulation of the retention interval and exposure to interfering information can differentially affect declarative memory as compared to nondeclarative memory performance. Conversely, changes in the modality of learning materials from initial exposure to memory testing, for example, by a change in the typeface of printed words or by a shift from auditory to visual presentation, can affect nondeclarative memory performance, whereas these manipulations have little affect on declarative memory. Yet other studies have dissociated declarative memory from nondeclarative memory by demonstrating stochastic independence, that is, lack of statistical correlation, between performance success in typical declarative and implicit expression of memory for the same items.

Studies on human Amnesia have also revealed numerous dissociations between performance in declarative and nondeclarative memory. In particular a profound impairment in declarative memory, but not nondeclarative memory, results from damage to the medial temporal lobe region. For example, following removal of most of the hippocampal formation and its associated medial temporal lobe structures, the famous patient H. M. suffered a profound impairment in recall and recognition that was remarkable in its severity, pervasiveness, and selectivity. H. M.'s memory was severely impaired regardless of the form of the learning materials or modality of their presentation. Yet, even the early observations on H. M. indicated that the hippocampal region was important to only some aspects of memory and spared other aspects of memory performance. With regard to the distinction between declarative and nondeclarative memory, the range of spared learning capacities in Amnesia includes motor, perceptual, and cognitive skills; sensory adaptations; and priming of perceptual and lexical stimuli. Even learning involving the identical materials may be either severely impaired or fully spared in H. M. and other amnesic subjects, depending on whether they were asked to use conscious recollection to recall or recognize the study phase, as is typical in most memory tasks, or whether memory was assessed by more subtle measures such as changes in response bias or speed after exposure to the test materials (for review, see Eichenbaum & Cohen, 2001).

We are only beginning to understand the structure of declarative memory and its neurobiological mechanisms. Some success in this understanding has come from the development of animal models of declarative memory, where behavioral, anatomical, and neurophysiological manipulations and measures can be pursued at a level of selectivity and resolution not possible in human subjects. In particular, recent studies in rodents have shown that damage to the hippocampus or its connections results in memory impairments that are severe in degree, pervasive in scope, and selective in the nature of the memory deficit, similar to observations on human Amnesia (Eichenbaum, 2000). Furthermore, these studies have offered insights into the nature of the cognitive mechanisms that underlie declarative memory. Thus, animals with hippocampal region damage are impaired at a variety of spatial, olfactory, and other learning tasks, but the memory impairment depends on the testing demands and on the type of memory expression, as it does in humans. Impairments are observed when subjects are required to combine and relate multiple independent experiences obtained across distinct events and then to express their memory flexibly by inferential use of information acquired in a situation different from that original learning.

For example, rats with hippocampal damage can learn to localize an important place in an environment when they are allowed to navigate directly to a particular complex of spatial cues. However, unlike normal rats, rats with hippocampal damage are impaired when they must learn to combine and relate spatial information obtained across different experiences, viewing the environment from different perspectives, or when they must express their knowledge of the relevant location from a new perspective. Similarly, rats with hippocampal damage can acquire responses to each of a set of particular odors. However, unlike normal rats, rats with hippocampal damage cannot acquire and inferentially express indirect relations among odor memories learned in separate episodes. These qualities of hippocampal dependent memory in animals bear similarity with William James's (1890/1918) characterization of conscious memory as involving numerous diverse connections among individual memories, allowing memories to be retrieved via many routes. Such a characterization suggests that the fundamental basis of declarative memory involves the networking of memories acquired across distinct episodes and the consequent capacity to surf such a memory network to retrieve and express memories in a flexible way.

DEFENSIVE PESSIMISM

Defensive pessimists strategically adopt and benefit from a negative outlook toward upcoming events or performances. Although they acknowledge a history of success in situations such as academic or social settings, they nevertheless enter those situations expecting the worst. Their pessimism is strategic because it serves two major goals: (1) a self-protective goal of helping the person brace for or be buffered from possible negative outcomes, and (2) a motivational goal of inducing increased effort and preparation in order to enhance the prospect of actually doing well. Defensive pessimism is measured using a scale called the Defensive Pessimism Questionnaire (DPQ; Norem & Cantor, 1986b), which has been extended for use in a variety of settings (Spencer & Norem, 1996).

Anticipatory Versus Retrospective Strategies

Defensive pessimists are characterized by anticipatory coping strategies, that is, those used *before* entering a performance setting. A hallmark of defensive pessimism is setting low performance expectations, which serves the self-protective goal. By thinking about how the worst might happen, they may cushion themselves preemptively against potential bad outcomes. If something bad does happen, defensive pessimists are able to think, "I expected it all along," making the outcome seem less deleterious. Convincing themselves that they will do poorly also serves a motivational goal by impelling them to redouble their efforts and preparation to ensure that they actually will do well. This helps to harness the anxiety or negative affect over possible failure (Norem & Cantor, 1986b; Sanna, 1996, 1998, 2000; Showers & Rubin, 1990).

Defensive pessimists' use of anticipatory strategies may appear ironic. First, they are very high performers, and in fact they have usually performed well in the past (Norem & Cantor, 1986b). Setting low performance expectations seems to be at odds with their actual performance histories. Second, convincing themselves that poor performances will happen does not actually make it happen. Low performance expectations are not self-fulfilling because of the buffering and motivational strategies (Norem & Cantor, 1986a).

Defensive pessimism is often contrasted with the strategy of optimism (Sanna, 1996, 2000; Spencer & Norem, 1996). Rather than using defensive pessimists' anticipatory strategies, optimists rely more on retrospective coping strategies, that is, strategies that are used *after* performance outcomes are known. Optimists do not set low expectations before performing as do defensive pessimists, but are more likely instead to engage in cognitive restructuring of performances after the fact (e.g., by using "self-serving attributional biases"; Cantor & Norem, 1989; Showers, 1992), particularly when those outcomes are poor.

Defensive pessimism also differs from true pessimism and depression; true pessimists and depressives do not use their negative outlooks strategically, and their ability to cope does not benefit from negative worldviews (Cantor & Norem, 1989; Showers & Ruben, 1990).

Mental Simulations as Strategies

Particular types of mental simulations appear to be a key part of defensive pessimists' strategies. Mental simulations can differ on the basis of timing (before versus after performance) and direction (better or worse than expected versus actuality; Sanna, 2000).

Defensive pessimists are most likely to use *upward-prefactual* thoughts as part of their preferred strategy (Sanna, 1996, 1998). Prefactuals are mental simulations of what may be. Upward prefactuals, which occur prior to performance, are alternative preoutcome mental simulations that are better than what one expects to actually happen (e.g., "If only I had more study time, I could do better on tomorrow's exam").

By comparison, optimists are likely to use *downward-counterfactual* thoughts as part of their strategies. Counterfactuals are mental simulations of what might have been (Sanna, Stocker, & Clarke, 2003). Downward counterfactual thoughts, which occur after performance, are alternative postoutcome simulations that are worse than actuality (e.g., "At least I bought the study guide, or my grade might have been worse").

In the case of defensive pessimists, low performance expectations function as an anchor from which mental simulations are generated. That is, if one expects the worst (to perform poorly), one's *alternative* simulated possible per-

formance outcome is most likely to be upward, or better than expected. Concomitant with upward simulations is higher anxiety and bad moods (Sanna, 1996, 1998). By comparison, optimists use downward counterfactuals after performing to maintain or restore good moods. In short, defensive pessimists use strategies that lower expectations and increase bad moods before performing, including upward prefactuals, but they do not use many retrospective strategies. Optimists do not use many anticipatory strategies, but employ downward counterfactuals retrospectively to maintain or restore good moods.

Strategy Usage and Effective Coping

Defensive pessimists effectively use their preferred strategies when coping with life events. However, when the use of strategy is unavailable or not possible, performance suffers. There are several examples of this. First, defensive pessimists prefer to think through (Norem & Illingworth, 1993) possible outcomes using such tactics as upward prefactuals. When thinking through alternate outcomes is interfered with by other demands, performance suffers for defensive pessimists, but not for optimists (Norem & Illingworth, 1993; Sanna, 1998; Spencer & Norem, 1996). Second, defensive pessimists' performance and coping are less effective when they are forced to focus on positive possibilities before performing (Sanna, 1996; Showers, 1992), because thinking about bad things is their usual tactic. By comparison, thinking about positive alternatives does not adversely affect optimists (Showers, 1992).

One reason defensive pessimists' strategies can be interfered with is that mental simulations and affect are linked (Sanna, 1996, 1999, 2000). When defensive pessimists are given encouragement and support (Norem & Illingworth, 1993), they ironically perform poorly. Encouragement puts them in good moods and takes them out of their normal strategy of having high anxiety and bad moods. Forcing defensive pessimists to think about good things (Sanna, 1996; Showers, 1992) may analogously put them in good moods and interfere with their usual strategies. However, being forced to think about negative possibilities puts defensive pessimists in bad moods, and they perform well. Directly putting them into bad moods (Sanna, 1998) also seems to improve performances. In short, defensive pessimists cope effectively using moods and mental simulations that facilitate their use of preferred anticipatory strategies.

DEINDIVIDUATION

In his classic book *The Crowd* (1895/1960), French sociologist Gustave Le Bon postulated the concept of a group mind. He suggested that in some circumstances persons lose their individuality and merge into the crowd. Such deindividuation was associated with a loss of inhibitions and a tendency to uncharacteristic and antinormative behavior. From a historical perspective, human beings have only slowly escaped from a deindividuated existence immersed in extended kinship relations, bonds, and tribes. In *Escape From Freedom* (1965) Eric Fromm examined the emergence of in-

dividuality in human history and the sense of uniqueness and freedom that accompanied this development. However, according to Fromm, individuation is accompanied by a feeling of isolation that often motivates people to join various groups.

Festinger, Pepitone, and Newcomb (1952) proposed that the person's focus on the group, which is associated with his or her attraction to the group, lessens the attention given to individuals. The focus on the group deindividuates its members, who are submerged and, in a sense, hidden within the group. Deindividuation, therefore, lowers the person's inhibitions toward engaging in counternormative actions. Thus, according to this formulation, attraction to a group increases deindividuation, which in turn encourages behavior that is normally inhibited.

In 1964, Ziller suggested that persons learn to associate individuation with rewarding situations and deindividuation with potentially punishing ones. A person learns to expect rewards for performing certain tasks well and wants to appear uniquely responsible for such actions. On the other hand, whenever the person expects punishment, there will be a tendency to hide or diffuse responsibility by submerging the self into a group. Ziller's emphasis was on the rewards and satisfaction that are gained through self-definition and uniqueness.

In still another version of deindividuation theory, Zimbardo (1969) argued that the expression of normally inhibited behavior may include loving and creative behavior as well as counternormative or negative actions. Furthermore, Zimbardo proposed that a large number of factors may lead to deindividuation, in addition to focus on the group or desire to avoid negative evaluation of moral responsibility. Among the deindividuating factors are anonymity (however created), the size of the group, level of emotional arousal, the novelty or ambiguity of the situation, altered time perspectives (such as during drug or alcohol use), degree of involvement in group activities, and so on.

All these factors lead to a loss of identity or self-consciousness which in turn causes the individual to become unresponsive to inhibiting stimuli and to lose cognitive control over emotions and motivations. As a consequence, the deindividuated person is less compliant to positive or negative sanctions from agents outside the group. Hence, behavior is less apt to conform to external rules and standards.

In 1980 Diener offered a further theoretical modification by associating deindividuation with self-awareness. Deindividuated individuals do not attend to their own behaviors and lack awareness of themselves as distinct entities. The result is a failure to monitor or reflect upon their own behaviors and a failure to retrieve appropriate norms of conduct from storage in long-term memory. Deindividuated persons also lack foresight, and their behavior lacks premeditation or planning. When there is little self-regulation, individuals are more apt to respond to immediate stimuli, emotions, and motives. Thus, their behaviors tend to be impulsive. In Diener's view the term *deindividuation* is a construct describing a set of relationships among situations, cognitive mechanisms, emotional states, and behavioral reactions.

A rather wide scope of antinormative behaviors has been associated with individuation and deindividuation. For example, drug abuse has been associated with social isolation from friends and family. Riots, lynchings, and other forms of mob violence have been attributed to deindividuation. A loss of inhibitions by members of encounter, marathon, and other noncognitive therapy groups has frequently been observed, and this may also be attributed to a loss of self-awareness.

DELTA RHYTHMS AND ACTIVITY

Electrical activity in the brain varies along qualitative and quantitative dimensions. Differences in the frequency of cortical rhythms have long attracted attention because of their relationships with normal and pathological conditions. This article focuses on delta rhythms and will be divided into three main sections. The biological basis of delta rhythms will be described first, followed by a brief discussion of its role in normal function, and then its involvement in selected neurological and psychiatric conditions.

Biological Bases of Delta Waves

Cortical rhythms, as measured by an electroencephalogram (EEG), largely reflect the algebraic summation of postsynaptic potentials of apical dendrites in cortical neurons. During periods of higher neural activity (e.g., alert

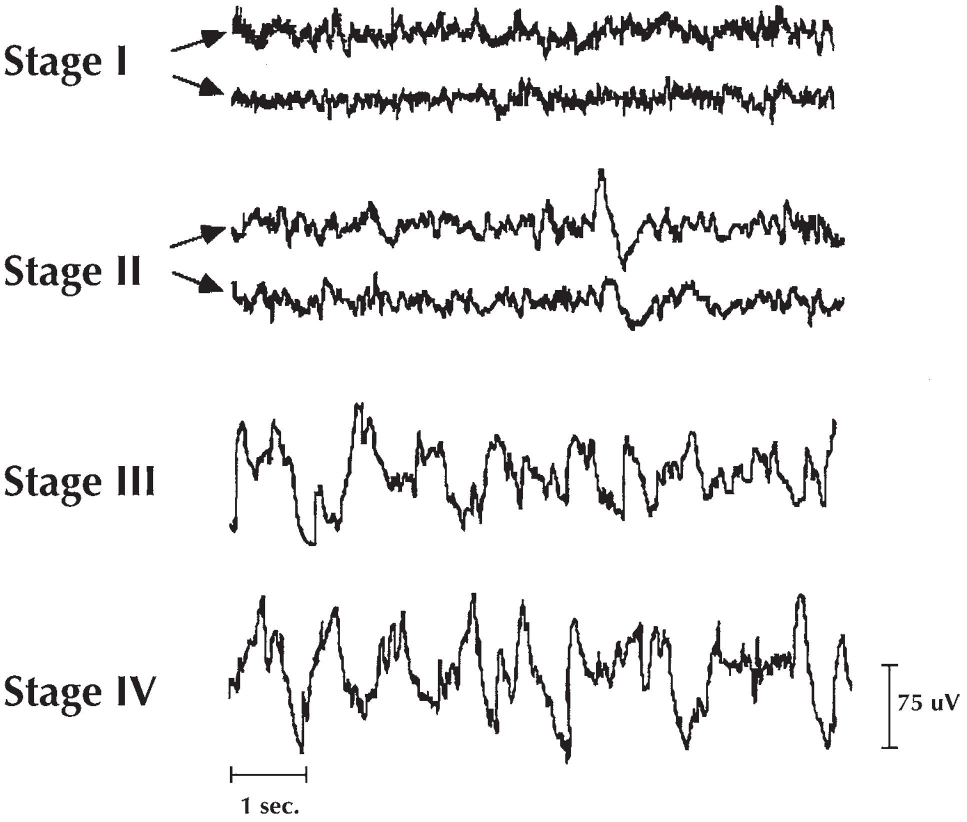

Figure 1. The stages of human sleep.
Note that the amplitudes of the waves increase while their frequencies decrease in the deeper stages (III and IV; noted as 3 and 4 in the text). This reflects reductions in cortical activity. Delta waves are most common in stages III and IV (see text).
Source: Figure courtesy of Dr. Robert Stickgold, Harvard Medical School.

wakefulness), waveforms are relatively heterogeneous and desynchronized from each other. Consequently, waveforms cancel each other out and appear on the EEG with low amplitudes and high frequencies. In periods of lower neural activity (e.g., deep sleep) waveforms are *relatively* more homogeneous and synchronized with each other. This synchrony appears on the EEG with higher amplitudes and lower frequencies. At least three distinct types of delta rhythms have been identified (Amzica & Steriade, 1998), including a slow one (less than 1 Hz) that is generated cortically in large neuronal networks, a second one that is generated in a clocklike fashion by thalamocortical neurons across a broader frequency (1–4 Hz), and a third one that is generated by cortical neurons with intrinsic bursting properties across a broader frequency. These separate rhythms integrate to produce polymorphic delta waves on EEGs in the range of 0.5–4 Hz.

Delta rhythms occur with the greatest intensity during deep sleep in humans (stages 3 and 4, that together is also termed *delta sleep;* see Figure 1) and are relatively localized to the prefrontal cortex (Buchsbaum et al., 1982). For this reason, the functions of delta waves are often linked to those of this region of the brain (Horne, 1993), although it should be stressed that delta waves are not limited to either one part of the brain or to one state of arousal. Recent data in mice show that delta power (i.e., a measure of delta EEG activity) is influenced both by duration of prior wakefulness and by genotype (Franken, Chollet, & Tafti, 2001).

Delta Waves in Normal Functions

Because delta waves occur with the greatest intensity and regularity during deep sleep (an EEG period, or epoch, is typically classified as stage 3 sleep if delta waves comprise at least 20% of the epoch, and it is classified as stage 4 sleep if delta waves comprise at least 50% of the epoch), their function has most often been linked to the function of sleep. The latter is a very complex issue that remains largely unsolved (Rechtschaffen, 1998), although it is likely that the primary benefits of sleep are to the brain (Horne, 1988).

In particular, the value of deep sleep has been related to the restoration of cerebral function, especially in the prefrontal lobes. Studies of sleep deprivation, for example, support this view because associated neuropsychological deficits are similar to those seen in frontal lobe dysfunction (e.g., diminished verbal fluency and intonation, poor planning, poor organization and encoding of new material—especially in regard to solving novel problems, diminished affect, vulnerability to interference and distraction, perceptual distortions, perseverations, and concrete thinking; e.g.,

Harrison & Horne, 1997; Horne, 1988; Kimberg, D'Esposito, & Farah, 1997). Moreover, when subjects are allowed to sleep freely following periods of deprivation (i.e., recovery sleep), most of the lost sleep is not made up, with the exception of deep sleep (and to a lesser extent, rapid eye movement sleep), which is then followed by the return of predeprivation levels of cognitive abilities (e.g., Horne, 1988).

Relationships between delta waves—usually measured in the context of deep sleep—and other biological processes are even less clear than they are in the restorative aspects of sleep. For example (Rechtschaffen, 1998), a variety of substances that stimulate immune responses, such as interferon alpha-2, interleukin-1, and tumor necrosis factor, also stimulate delta sleep (e.g., Krueger, Shoham, & Davenne, 1986), which underlies the hypothesis that immune responses are impaired by the loss of delta sleep and facilitated by its presence. The effects are far from general, however, with little direct evidence to link delta sleep to immune function (e.g., Benca & Quintans, 1997; Rechtschaffen, 1998). Similarly, hypotheses of causal relationships between pain thresholds (notably in fibromyalgia syndrome) and delta sleep remain unconfirmed (Older et al., 1998).

Delta Waves in Pathological Functions

Delta waves are related to pathological functions in at least two ways. The first of these involves the presence of abnormal delta activity. For example, impairments in cortical areas (e.g., due to deafferentation, abnormal development, or necrosis) promote delta waves in regions contiguous to cortical tumors (Amzica & Steriade, 1998), in Down syndrome (which reflects slow and deficient brain development; Kaneko, Phillips, Riley, & Ehlers, 1996), and in cerebrovascular disease (Inui, Motomura, Kaige, & Nomura, 2001). Because these rhythms (during wakefulness) are often related to dysfunction in specific areas, they may facilitate intervention strategies, such as the presurgical localization of temporal lobe (Jan, Sadler, & Rahey, 2001) and extratemporal lobe (primarily frontal; Geyer, Bilir, Faught, Kuzniecky, & Gilliam, 1999) epilepsies.

A second way in which delta activity is related to pathological processes is by its absence or unexpectedly low levels during sleep. This occurs in psychiatric disorders that include, for instance, Schizophrenia and depression. Several studies that augmented visual EEG scoring with automated counts of delta activity showed reduced delta waves in Schizophrenia, especially in the greater than or equal to 1–2 Hz range (Ganguli, Reynolds, & Kupfer, 1987; Keshavan et al., 1998), although not all patients demonstrate the abnormality (e.g., Hoffmann, Hendrickse, Rush, & Armitage, 2000). These findings are interesting in that Schizophrenia provides another example of a disorder that often involves prominent frontal lobe pathology, related neuropsychological deficits (Seidman et al., 1996), and impaired delta activity reductions. Moreover, deficits in delta activity occur in major depression (Benca, Obermeyer, Thisted, & Gillin, 1992; Hoffmann et al., 2000), which may also include frontal lobe dysfunction. Although other, non-delta sleep deficits occur in these disorders as well, these findings raise the possibility that deficits in delta activity during sleep might serve as markers for psychiatric as well as neurological disorders.

DEPENDENCY

Dependency is the seeking of identity, support, security, or permission from outside the self. The dependency object may be another person; a social unit such as an extended family or a religious or fraternal order; an entity beyond the five senses such as a spirit guardian; or even a belief system in itself, for example, nonviolence, to which the dependent is devoted and from which the dependent receives nurture in return.

By definition, dependency is reciprocal. The dependent seeks, expecting and receiving a dependency response: To give is to receive and to receive is to give. It is also obligatory: Dependents are *expected* to seek and receive return support. Failure to participate in this circle of obligation may result in a range of responses from verbal disapproval to ostracism.

Dependency differs from the related process of interdependence in which separate entities reciprocally seek identity, support, security, or permission from one another.

In "dependency societies," such as Japan, the fledgling ego is taught to defer inside a vertical authority system. The ideal of conformity is intended to strengthen the individual's sense of self-respect. In "independence societies," such as modern mainstream America, the fledgling ego is expected to move out of obligatory relationships in a horizontal authority system, rather than to defer. The ideal of self-focus is intended to strengthen the individual's sense of self-respect.

Key characteristics of dependency are bonding, obligation, reciprocity, trust, continuity, and involvement. Every culture or subculture defines "normal" dependency on the basis of its own value system.

Whereas Western thought minimizes continuity between the living and ancestors, dependency cultures tend to consider discontinuity as threatening.

Even though there are cultural variations, there seem also to be certain universals in dependency. Key characteristics fall into three clusters.

The first cluster may be viewed as negative dependency, which hinders psychosexual development, crippling the ability to handle a variety of life situations. The second cluster can be considered positive, enhancing the maturing process by aiding individuals and groups to function in ways that support their sense of well being. The third cluster relates to an absence or termination of dependency relationships, which may also cripple development.

It is useful to divide dependency theory into three culture-time phases: (1) preliterate, tribal, and folk (beginning to present), (2) modern colonial (1500–1945), and (3) postcolonial (1945 to present).

Preliterate, Tribal, and Folk Studies

Early ethnological studies tended to view dependency as structural networking based on tribal, village, folk, and extended family patterns that were seen, on the whole, as positive. They were thought to reflect security and other needs in a life setting severely limited by a prescientific worldview and technical development.

In such a society individuals define themselves or are defined as they relate to others, rather than by how they fulfill or express themselves. Success in these interactions is considered the most important measure of mature self-expression.

Modern Colonial

The interruption of traditional dependency patterns has been a major and often underestimated effect of colonial contact since the fifteenth century. As Mannoni has shown, a major factor in the conquest of native peoples was their own tendency to transfer dependency expectations from familiar authority figures to European authority substitutes.

Aggressive European cultures exploited native dependency while at the same time exporting values of independence, individualism, and progress, which did as much to weaken native resistance as the horses of Cortez or the firearms of the British. With its emphasis on competition, the Protestant work ethic dealt a heavy psychological blow to traditional notions of reciprocity, obligation, and trust. Under long-term colonization, the native personality is thought to have been severely stressed by the need to reconcile warring dependency-belief systems.

During this same period in the Western world, dependency appears to have been systematically downgraded to neurotic behavior. Sigmund Freud theorized that the helplessness of the infant was the source of lifelong dependency bonds against which the maturing ego must implacably struggle.

Furthermore, Freud held that the psychological structures and functions of societies paralleled those of individuals. In modern thought—strongly influenced by Freudian theory—individuals must struggle to break free from dependence on groups as well as from a variety of others, beginning with Mother. What had earlier been seen as reciprocity came to be regarded as helplessness.

Postcolonial

In the Western world since about 1945, the belief has begun to emerge that undue stress on independence, change, and competition has contributed to massive alienation, anomie, and even morbidity rates. One response has been a trend toward the reinterpretation of dependency, as seen in a variety of recent developments. Carl Rogers, through his work on group dynamics, has encouraged a variety of lay and professional approaches that stress dependency interaction. More recently, "networking" has become a major drive among persons who recognize their need to relate to other individuals, especially in urban settings.

Another dependency development is affiliated families, in which nonblood kin members of two or three generations pool their needs and resources in a common dwelling or at least in the same community.

J. Gurian

DEPENDENT VARIABLES

Dependent variable is a term used in research methods and refers to the attribute being measured. In experimental research the dependent variable is what is being assessed to determine the effect of manipulating an independent variable. The dependent variable may involve behavioral, physiological, or social characteristics depending on the nature of the study. It may involve assessment of performance, such as the amount of information a subject might learn as measured by the number of correct responses on a test. A dependent variable is what is being measured to ascertain the effects of some treatment in an investigation or to use as a description of the status of subjects in the study. For example, suppose two methods of math instruction were being compared: the dependent variable might be the number of correct responses on a math test administered after instruction is completed.

The choice of a dependent measure is often given inadequate attention when researchers are designing studies. However, selection of an appropriate dependent variable is very important to the overall strength, outcome, and interpretation of an investigation. A number of matters should be considered in determining the appropriateness of the dependent variable selected.

One obvious concern is that a dependent measure should reflect the construct being studied. If a researcher is investigating anxiety, the dependent variable should relate to the construct of anxiety. A dependent variable should also be both sensitive and reliable in the context of the phenomenon under study. The measure should be sufficiently sensitive to detect accurately behavioral or performance changes when they occur. The dependent measure should be able to reflect such changes in a reliable fashion. Generally, a researcher will select the most sensitive and reliable dependent variable possible. The only circumstance when this rule of thumb is not appropriate is when such a measure is obtrusive, that is, when the act of obtaining the measure alters a subject's behavior. If using a particular measure appears to be obtrusive, another dependent variable may be preferred so that the data obtained are not contaminated. Thus, the measure of choice is one that is maximally sensitive, reliable, and unobtrusive.

Another consideration related to selection of a dependent variable involves avoiding ceiling or floor effects in the data. A ceiling effect occurs when the performance range of the task is limited so that subjects "top out." A floor effect reflects a task so difficult that many subjects cannot perform the task at all. Ceiling and floor effects generate inaccurate results or artifactual data. In circumstances where either ceiling or floor effects exist, the data reflect the limits of the task rather than subjects' ability to perform.

DEPRESSION

Description

In the United States, the word *depression* refers to everything from a transient mood state (feeling down) to a clini-

cal disorder, Major Depressive Disorder (MDD). In order to receive a diagnosis of MDD, a person must experience marked distress and a decrease in level of functioning. In addition, the 2 weeks preceding the examination must be characterized by the almost daily occurrence of a dysphoric mood (e.g., sadness) or a loss of interest or pleasure (anhedonia) in almost all activities. The individual must also experience at least four (only three if both dysphoric mood and anhedonia are both present) of the following seven symptoms nearly every day for the 2-week period: significant weight change or change in appetite; Insomnia or Hypersomnia; psychomotor agitation or retardation; fatigue or loss of energy; feelings of worthlessness or excessive or inappropriate guilt; decreased concentration or indecisiveness; and suicidal ideation, plan, or attempt (*Diagnostic and Statistical Manual of the American Psychiatric Association*). Related disorders (i.e., other Mood Disorders) include Bipolar I and II Disorder (manic-depressive disorder), dysthymia, and cyclothymia.

Prevalence and Costs

MDD is the most commonly diagnosed psychiatric disorder among adults, with lifetime prevalence rates of 20–25% for women and 9–12% for men. At any given point in time, the prevalence rates are about 6% for women and 3% for men. MDD is fairly rare among children, but it begins to manifest itself at puberty. Depression has been diagnosed with increased frequency among young people, so that in the current 16-to-25 age group, about 20% have already suffered from a MDD. After late adolescence, the prevalence rates and gender differences are fairly constant over the human life span.

Depression tends to be a cyclical disorder. Among those who have one episode, the probability of a second episode is 50%, and among those with two episodes, the probability of a third episode is 75–80%. After the third episode, the disorder is likely to plague the person on a chronic basis, although episodes of the disorder may come and go even without treatment. The episodes are painful for the individuals with the disorder and those around them. As noted, the disorder interferes with functioning in both social situations and jobs. The costs are enormous to both the individual and society; for example, MDD is regularly rated among the top five most expensive health problems.

Treatments

There are two major approaches to treatment of MDD—biological interventions and psychotherapies. The major biological intervention is antidepressant medications. The first major classification of antidepressants was called *tricyclics* because of the chemical structure of the medicines. Included in this group were such familiar medicines as amitriptyline (Elavil), imipramine (Tofranil), desipramine (Norpramin), and nortriptyline (Pamelor). These medications worked with about 55–65% of patients with MDD, but they have fairly severe side effects, including blurred vision, constipation, and orthostatic hypotension; furthermore, an overdose of these medications is likely to be lethal. Thus, they are currently used less frequently as a first line of treatment. Another class of antidepressant medications is the monoamine oxidase inhibitors (MAO inhibitors); examples include phenelzine (Nardil) and tranylcypromine (Parnate). These medications are as effective as the tricyclics for MDD and probably slightly more effective for a form of the disorder called *atypical depression* (e.g., symptoms of mood reactivity, extreme sensitivity to rejection, extreme fatigue, increased sleep, and weight gain or appetite increase). However, MAO inhibitors necessitate abstinence from several popular foods, so they are not very well tolerated. By far the most popular class of antidepressant medications currently is the selective serotonin reuptake inhibitors (SSRIs), which includes fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), and citalopram (Celexa). These medications work with 60–70% of individuals with the disorder, and the side effects are *relatively* minor. However, one major drawback to the SSRIs is their fairly frequent side effect of inhibiting orgasm. There are several other less frequently utilized antidepressants, which do not fall into one of the preceding classes. One of those is buproprion (Wellbutrin), which may not be quite as effective as some of the other antidepressants, but it does have the advantage of facilitating sexual performance in some patients. For extremely difficult to treat depressions, electric convulsant therapy (ECT) and transcranial magnetic stimulation (TMS) may be employed. The latter therapies work very well, but there are fairly severe side effects, and the rates of relapse following the treatments are fairly high.

There are innumerable psychotherapies, but there are two that have been fairly extensively evaluated as treatments for MDD. Both of these therapies are short-term (16–20 sessions), conducted over a period of 12–16 weeks. Both therapies focus on current life problems and are fairly directive (i.e., the therapist takes an active role in identifying and suggesting possible solutions to problems). The first of these is interpersonal psychotherapy (IPT). This therapy was designed to address interpersonal difficulties associated with MDD and focuses on one or more interpersonal problems. The topics of therapy include life transitions, losses, lack of social skills, and role conflicts.

The second effective psychotherapy for MDD is cognitive-behavioral therapy (CBT). This therapy focuses on the behavioral deficiencies (e.g., a lack of social skills) and cognitive styles (e.g., the belief that the depressed person causes bad things to happen, has always caused bad things to happen, and causes bad things to happen in many areas of his or her life) associated with MDD. With outpatients suffering from MDD, IPT and CBT are about equally effective.

Each is about as effective as antidepressant medications for mild to moderate depressions. Current studies are under way to determine if these psychotherapies are as effective as the antidepressant medications for more severe depressions. The limited available data suggest that a combination of antidepressant medications and one of these psychotherapies is both the most effective and the most enduring treatment for MDD.

Pharmacological interventions with children with MDD have been very disappointing; however, recent work has shown that fluoxetine (Prozac) is effective with adolescents who are age 15 or older. CBT has been used in small-sample studies with children, and it seems to be reasonably effective. CBT has been implemented in both the school and family settings.

At least two large research projects have suggested that behavioral marital therapy is an effective treatment for MDD when the depressed person is a partner in an unhappy marriage. It has been found that 50% of married depressed individuals are in unhappy marriages and that 50% of individuals in unhappy marriages are depressed. Thus, behavioral marital therapy may be useful to many married patients suffering from MDD.

One of the problems that has plagued the treatment of MDD is that a fairly large percentage of successfully treated individuals suffer from a relapse or recurrence of the disorder. Because the relapse rate is so great when antidepressants are taken for a fairly brief period of time (e.g., 3 months), it is strongly recommended that once an antidepressant medication is taken, it should be continued for at least 9–12 months. Combining antidepressant medication and psychotherapy (IPT or CBT) appears to decrease the relapse rate following treatment. It does appear that the most effective treatment for recurrent (three or more episodes) MDD is likely to be continued antidepressant medications.

Because of the increasing rates of MDD among young people, it is becoming increasingly important to prevent first episodes and recurrences of the disorder. Prevention programs, focused on individuals with some but not all the symptoms of MDD and individuals with pessimistic cognitive styles, have shown some promise. Small studies also suggest that combined CBT and IPT for individuals who have had an episode of MDD but are not currently depressed may decrease the recurrence rates of MDD.

DEPRESSION AND BIPOLAR SUPPORT ALLIANCE

The Depression and Bipolar Support Alliance (DBSA) is the largest patient-directed, illness-specific organization in the United States. Incorporated in 1985 and headquartered in Chicago, DBSA has a nationwide grassroots network of chapters and support groups. It is governed by a 15-member board of directors and guided by a 65-member scientific advisory board comprised of the leading researchers and clinicians in the field of mood disorders. The organization does not endorse or recommend the use of any specific treatment or medication, but rather encourages patients to make informed choices with their health care providers.

DBSA's mission is to improve the lives of people living with mood disorders. Efforts to accomplish that mission include:

- *Encouraging people to seek diagnosis and treatment.* By communicating information about depression and bipolar disorder, especially about symptom recognition, DBSA encourages people to take the first step to seek help and assists them in adhering to their treatment plan once a diagnosis has been made. DBSA's programs and services also reduce the fear and isolation associated with mental illness by delivering a strong message of hope and community, and reinforcing the critical message that mood disorders are real, treatable illnesses, not personality flaws or character weaknesses. Visitors to the organization's web site, www.DBSAlliance.org, can also take the Mood Disorder Questionnaire (MDQ), the first bipolar disorder self-assessment tool ever available, as a way to take their first steps in seeking diagnosis.
- *Raising awareness to eliminate stigma.* The stigma surrounding mental illnesses is so strong it can prevent people from seeking help, weaken their already fragile self-image, or put their employment in jeopardy. It has also hampered efforts to achieve insurance parity for mental illness. DBSA effectively battles stigma through public education. Its public service announcements have been broadcast on the radio and have appeared on television and in dozens of national magazines. The organization's educational video, *Dark Glasses and Kaleidoscopes,* can be rented free of charge at Blockbuster Video stores across the country. Its web site features stories of real people and how they have worked to overcome stigma and the challenges of their illness. In addition, DBSA keeps a close eye on the media and responds to stigmatizing material. The organization keeps its constituents informed and encourages them to respond to stigma in their communities.
- *Enhancing health care professional and patient communication to maximize treatment success.* The cre-

ation of effective dialogue between patients and professionals can lead to a higher quality of care and more positive outcomes. Health care providers will be better able to care for and communicate with patients if they can understand mood disorders from the patients' perspective. In addition, patients can become empowered to play an important role in the management of their own illnesses by receiving information about treatment options, possible side effects, and expected outcomes. DBSA provides this information in a variety of free brochures, and offers books and audio and video tapes for purchase, all of which are carefully reviewed for accuracy and relevance.

- *Answering questions about the illness, treatment, and side effects.* It is sometimes difficult for patients to understand what health care professionals are saying. The information DBSA provides is presented in a clear, easy-to-understand way. Patients who receive clear, jargon-free information about treatment and side effects are much more likely to continue treatment as prescribed. DBSA's web site and local DBSA support groups are often the first places people go for answers to their questions, and can be lifelines for patients living outside major metropolitan areas.
- *Providing groups for peer-to-peer and family member support.* The more than 1,000 DBSA peer-run support groups motivate people to follow treatment plans; help patients understand that their illnesses do not define who they are; provide a forum for mutual acceptance, understanding, and self-discovery; and offer the opportunity for patients and their families to reach out to others and benefit from the experience of those who have "been there." Many support group participants say that their groups have brought meaning back to their lives and have been the first place where they were able to connect with caring friends who truly understood them.
- *Serving as a champion for mental health care reform.* DBSA is constantly working to change laws, increase funding for research, and advance the fight for such critical issues as patient confidentiality and insurance parity. DBSA keeps constituents informed about pending legislation through its newsletter and web site, and it offers ideas and assistance for writing letters to members of Congress to make constituents' collective voice heard.
- *Encouraging patient-centered research that results in better treatment and eventually facilitates a cure or prevention.* DBSA keeps lawmakers and government decision-makers aware of the great need for increased research, and therefore increased funding. In addition, the organization represents and protects patients by serving on the advisory boards of many clinical trials. DBSA also convenes annual conferences of preeminent mood disorder researchers to share knowledge in the field and come to consensus on best practices. The organization also gives awards to outstanding researchers.

As a patient-run and patient-focused organization, DBSA plays a critical role in advocating for the individuals and families touched by these devastating illnesses. In addition to raising awareness, encouraging timely and accurate diagnosis and treatment, providing patient-focused information to enhance doctor/patient communication, advocating for health care reform, and helping people to share experiences with our network of support groups, DBSA provides hope. The hope that recovery is possible and that others can understand their pain makes a lifesaving difference to the millions of patients and their families struggling with mood disorders.

DEPROGRAMMING

J. Clark defined extremist religious cults as being characterized by the following: (1) wealthy living leaders who consider themselves to be messiahs or claim to possess special powers, (2) philosophies based on a system of dogmatic and absolutist beliefs, (3) a totalitarian system of governance, (4) requirements to obey group regulations without question, (5) a strong emphasis on acquiring wealth for the cult, and (6) little concern for the welfare of the individual cult member.

Potential converts are rarely made aware of these characteristics but are usually given information quite different or even in direct opposition to what actually takes place. M. Singer and R. J. Lifton claim that once recruits are drawn far enough into a cult to be affected by group pressure, they are subjected to brainwashing strategies.

The end product of the indoctrination process is simplistic and stereotyped thought. As in hypnotic states, thought content is controlled largely from without rather than from within, resulting in blind obedience to the cult leader.

Comprehensive personality change can be effected by extremist religious cults within a few days to a few weeks, while J. Clark reported that after 4 to 7 years of cult life such changes may be irreversible.

Deprogramming consists of the facilitation of critical, flexible, creative, and independent thinking, and the correction of misconceptions about cult life. This is accomplished by encouraging the cult member to examine the cult ideology in the light of logic and empirical data. This examination can be catalyzed through a series of leading

questions whereby the recruit is guided toward a systematic examination of issues on the basis of data available through his or her own life experience.

Straightforward filling of information gaps is also useful. For example, recruits may not know the true identity of the group they have joined, the fact that creative community projects give nothing to the community, that they will be expected to devote their life to the group, or that their marriage partner and the date of the marriage will be chosen for them. Of particular usefulness is a description and explanation of the indoctrination process.

Throughout the process the recruit's curiosity, questioning, and reasoning builds momentum until a point is reached that marks a change in the process. During this time the recruit may suddenly pause and become quiet and reflective, or express signs of shock. The recruit then usually "snaps." This moment is characterized by such sensations as tingling and shaking. Affectively, it may involve agonized crying and fear; cognitively, it is associated with a sudden change in worldview and a decision to leave the cult.

Treatment does not end with the snapping moment because for a period following it termed the *floating phase,* a chance meeting, phone call, or even a word may result in the recruit snapping just as quickly back to the cult worldview. To prevent this, individuals usually require continued support and guidance until critical thought capacities are strengthened enough to be self-supportive.

George K. Lockwood

DEPTH PERCEPTION

We perceive the world around us as containing different objects that are separated from each other and from us by varying distances. This three-dimensional awareness of the space around us is termed *depth perception* and is made possible by the use of several sensory input channels that provide the cues indicating the respective distances between us and these other objects in space. Human perceivers attend primarily (in most cases) to visual depth cues that are typically classified as either monocular (requiring at least one eye for cue interpretation) or binocular (requiring at least two eyes).

Monocular Cues

Through visual experiences we have learned to associate familiar objects of known size as being near or far depending upon the consequent retinal image size. Thus, *size* is one cue. Similarly, near objects tend to be more clearly seen than distant objects because of atmospheric degradation; thus *clarity* is another cue. *Aerial perspective* is a special case of the loss of clarity found with increasing distance above viewed objects. *Linear perspective* is a cue based on multiple familiar objects subtending smaller angles as they represent greater viewer-to-object distances. Linear perspective is illustrated frequently by the apparent decrease in road width seen as the road diminishes into the distance. An object partially positioned behind another (opaque) object gives rise to the cue of *interposition,* resulting in a partially seen view of the more distant object. As a consequence of *accommodation* (changing thickness of the lens as one focuses the eye for varying distances), kinesthetic feedback may indicate different (short-range) distances. *Motion parallax* is a cue based on the greater amount of retinal image movement for close objects than for far objects when the eye moves laterally. *Chromostereopsis* (illusion of depth that results from changing the focus of the eye for coplanar objects of different hues because of chromatic aberration) is a nonveridical form of apparent depth that may be noticed on computer color monitors. A sudden increase in size—called *looming*—results in a retinal image that may be veridical or illusory in indicating object approach.

Binocular Cues

Two eyes separated in space receive different views of the visual field. These different views form slightly different images on the separate retinas of the eyes and serve as the basis for the cue of *retinal disparity.* In human visual development this cue becomes effective (on average) at an age of 4 months (although in cases where there is a failure of the eyes to work together, as in uncorrected strabismus, the child may, if not functionally blind in one eye, nevertheless become stereoblind). When the two eyes are directed toward and become focused upon objects at varying distances, several changes occur. Specifically, as the distance to an object is reduced, each eye rotates inward through the activation (mainly) of the medial rectus and inhibition of the lateral rectus extraocular muscles of the eye. This is the binocular cue of *convergence.* A second physiologically linked response is that of *accommodation* (mentioned previously as a *monocular cue*). Both of these provide kinesthetic feedback indicating depth. Pupillary constriction occurs as an associated third response with the increased depth of field possibly serving as an additional depth cue. Several of these cues may be simultaneously operating, each one corroborating the others. It is difficult experimentally to identify which cues are operating at a given time.

Visual depth perception is studied in several ways. One approach is to have the subject (under binocular or monocular conditions) adjust a rod or needle such that it is equally distant relative to a standard. The visual cliff (a platform device with a glass floor extending out over an apparently deep side and shallow side) can be used to test depth perception in human and nonhuman subjects by ascertaining the amount of preference for the shallow side. Three-

dimensional perception can be provided by the stereoscope, which presents two nearly identical views separately to the two eyes. A later development has been Bela Julesz's invention (1971) of random-dot stereograms: computer-generated patterns of random dots with pattern pairs that are identical except for a laterally displaced region. This region, when viewed with a stereoscope, appears to stand above or below the rest of the pattern.

Auditory depth cues are used by blind people who can approach and stop before colliding with a wall by (unconsciously) attending to reflected sounds. Echolocation in bats and cetaceans represents an elaboration of this capability. Additional auditory cues for depth are amount of reverberation, spectral characteristics (atmospheric absorption is greater for higher frequencies), motion parallax, and relative loudness of known sounds.

Depth cues provided by other senses include proximity detection because of the strength of a familiar odor, thermal detection in pit vipers, and the electric field sensitivity found in some fish.

DETERMINISM AND INDETERMINISM

The concept of determinism in philosophy has in it the element of necessity: Things must be just as they are because of antecedent causes. This notion is central to science, which maintains that, were one to know all factors involved in some forthcoming event, one could predict it exactly; or conversely, if an event occurs, that it is inevitable. Every thing and event in creation is the result, and will always be the result, of natural laws that can be determined by means of the scientific method.

When it comes to human behavior, an interesting set of alternative positions has been established that has real relevance outside psychology as a science or profession and that relates to general human behavior and institutions, including the laws of society and the dogmas of religion. What has occurred is an interesting set of contradictions. As noted, scientists view life as determined and generally believe in the inevitability of behavior: Were one to know everything about an individual, one could predict his or her every movement. However, throughout the history of society the common-sense view has been one of individual responsibility.

Indeterminism generally is taken to mean that the individual has freedom of choice, that people can predict the consequences of their actions and can decide how to operate, for example, in terms of their own selfish gain versus the good of the community. The purest example of indeterminism is the belief in free will, which holds that all conscious behavior is decided by responsible people. The laws of most societies and the dogma of many religions, especially the Judaeo-Christian ones, are based on the notion of individual responsibility: The consequences of punishment—whether in this world or in the next—are justified in terms of a person's moral judgments and behavior.

Psychologists take a variety of positions in this age-old controversy. Strict behaviorists tend to be strict determinists, whereas those with an existential bent tend to be indeterminists. However, perhaps in an illogical manner, most psychologists sit on both sides of this fence, asserting as part of the scientific method the necessity of determinism, but nevertheless operating in terms of indeterminism.

Fairly recent events in the world of physics cast doubt on the scientific legitimacy of determinism. Essentially, the issue has to do with the impossibility of determining at the same time the momentum of an electron particle as well as its position. Apparently, there will always be an area of uncertainty. Werner Heisenberg, who received the Nobel prize in 1932, developed from this observation what is generally known as the Heisenberg indeterminacy principle, demonstrating that Newtonian physics simply does not apply at the level of atoms. If we view the single human as the equivalent of an atom, we may now say that, while determinancy is true for the human species, leading to a deterministic nomothetic position, indeterminancy is also true for the human individual, whose behavior would be only partially explainable in terms of preceding events. In other words, the individual is impossible to predict with complete success.

DEVELOPMENT OF HUMAN SOCIAL BEHAVIOR

Social behavior occupies a place of paramount importance in the lives of human beings and its development therefore commands attention. Social behavior encompasses a human being's interaction not only with other persons but also with the world of things, which have acquired their meaning and status from the customs and practices of the culture.

The development of social behavior depends on and keeps pace with the development of such biological and psychological processes as maturation, perception, attention, memory, and learning, as these processes are modified by experience. Further, its development depends on the same processes of learning (taken in its broadest meaning) as the development of any other class of behavior, including trial-and-error learning, conditioning and the law of effect, social learning theory with its emphasis on imitation and modeling, and the comprehension of language. Thus, no child, no more than any human being, can behave socially in the absence of motor, cognitive, or linguistic skills.

Social behavior is by definition an interactive process; the behavior of any partner to the interaction modifies the behavior of the other person, even as it is being modified by the response of the other person. The interaction begins at birth, hence it may fairly be claimed that the human infant qualifies from birth as a social being.

Not only do human infants, requiring constant provision and care, depend for their survival on the ministrations of others, but they are in fact treated as social beings at birth. Mothers and fathers, for example, smile and vocalize to their newborn infants, and an analysis of the speech of hospital personnel to newborns provided ample evidence that even these unrelated persons viewed and treated newborns as fellow human beings.

From birth on, the uneven development of the human infants' sensory and motor systems, compared with the young of many other mammalian species, plays a special role in the development of their social behavior. In their ability to respond to visual, auditory, and tactile stimuli, they resemble precocial animals; in their inability to locomote and so secure nourishment or mingle with other members of their species by their own efforts, they resemble altricial animals. During the long period until effortless locomotion is achieved, what they see and hear, the objects and persons with whom they have contact, as well as the routines of care, are provided by their parents. The gaze, speech, smiles, and other acts of caretakers not only evoke responses from the infants but just as often follow (are contingent on) the infants' looking at them, smiling, vocalizing, crying, and so on.

Development During the First 6 Months

Scales of infant development document many early social behaviors. Infants pay attention to people who approach them, show facial brightening and smiles in response to a person who smiles and talks to them, and are quiet when held. Even in the first month or so of life they vocalize in response to another's vocalizations. By 16 weeks of age they are already initiating social play. They have also learned that their crying brings people to their side, even as people learn what they should do to alleviate the cause.

During this early period, infants achieve the major accomplishment of learning to distinguish between the animate and the inanimate, between people and things. Although many objects in the world provide as varied visual and auditory stimulation as do people, people respond more often to the infant's behavior and, being human, their responses are more variable and less predictable. Especially the faces of people, on which infants fasten very early in life, not only present an ever-changing set of stimuli, but are almost always accompanied by speech appropriate to their own feelings and actions, as well as to those of the infants. It is people, finally, who minister to the infants' basic biological needs.

The infants' ability to distinguish between familiar and unfamiliar persons constitutes another major accomplishment of these early months. Although infants this young respond positively to all persons, the social responses to familiar persons are more expansive and come more readily.

These social accomplishments reveal the infants' growing perceptual abilities and the presence of a considerable memory.

The Second 6 Months

The social accomplishments of the infants' earliest days become richer and more varied as their perceptions deepen, their motor skills improve, and their knowledge increases. They repeat behaviors others laugh at, imitate sounds, and respond to their names. They learn the rules of the game of give-and-take and, whereas at 6 months of age they enjoy playing peek-a-boo, by 12 months of age they are already initiating a number of simple games.

About midway in this period infants begin to show distress when separated from their mothers and often from their fathers—a behavior that reaches prominence especially when they are ill or otherwise upset. The phenomenon was labeled *separation anxiety* by Spitz and described in hospitalized children by James Robertson and John Bowlby. These observations gave rise to the concept of attachment first sketched by Bowlby. Subsequently, attachment was studied empirically by Mary Ainsworth. Although Robert Cairns supplied a straightforward learning theory explanation of the disruption of behavior caused by the removal of familiar stimuli, the reliance of the concept of attachment on psychoanalytic and ethological theory remains strong.

As the concept evolved, component behaviors were delineated. The infant's seeking to maintain proximity to the

mother, by staying close or by following her, was proposed as the primary indexing behavior. Then, as everyday observation showed that infants often wandered away at the beck and call of an enticing environment, such behavior was incorporated and labeled *exploration from a secure base.* The other component behaviors included the aforementioned distress at separation from the mother and the display of fear in the presence of strangers. In a later development, three types of attachment—secure, avoidant, and resistant—were proposed, based on differences in the infants' responses to the mothers' return after a series of experimentally manipulated events that ended in the infants' being left alone in an unfamiliar environment. The nature of the infants' responses was attributed to differences in the mothers' sensitivity to the needs of their infants.

Attractive as the concept of attachment is, some qualifications are in order. The concept scants the differential contribution to the interaction made by different infants; infants vary as much as caretakers, and both contribute to the interaction. Also, infants are not always cared for exclusively by their mothers, and room must be allowed for attachment to other persons, as first proposed by Rudolph Schaffer and Peggy Emerson. Furthermore, infants not only crawl away from their parents, but do so in most unusual and hence unfamiliar settings (e.g., airports). Even when free to follow a parent, they often stop first to play with toys and on occasion will follow an unknown person. Thus, even for infants, a world of difference lies between a voluntary and a forced separation from loved ones. Finally, although infants may scrutinize unknown persons more intently and do not always smile at unsmiling persons, they do not show fear. Approached playfully or even normally, most infants respond positively. When fearful responses are reported, they have been experimentally produced by socially invasive procedures.

As children approach their first birthday, they show unmistakable signs that they are becoming aware of themselves as actors among other actors, signs that suggest the beginnings of a self-concept. Even when infants repeat an act the parents laughed at, a dawning sense of themselves as individuals can be surmised. A similar claim can be made for the behavior, common at about 10 months of age, of the infants' holding objects out to other persons with the apparent intent of drawing their attention to the object—a behavior followed sometimes now, but always in the second year, by actually giving them objects. Such behavior had long been practiced in the give-and-take game and is so well consolidated in the next few months as to qualify as a gesture of sharing one's possessions with another. Drawing other persons' attention to distant objects by pointing with the index finger is a related accomplishment. Now, when they themselves point to interesting spectacles, they also vocalize and look back at the person's face as though to check that the message is received. Infants, then, recognize other persons not only as separate from themselves, but also as persons with whom they can share an experience.

The Child's Wider Social Environment

Even though fathers generally have spent less time with their infants than mothers and have been less responsible for meeting their moment-by-moment needs, what actually does occur during these intermittent interactions is especially highlighted. As actual studies of the nature of the interaction between fathers and infants now reveal, fathers are just as responsive to their newborn infants as mothers. Although fathers are as capable as mothers in ministering to the physical needs of their offspring, and often do so, their style undoubtedly differs from that of mothers. Certainly differences in how mothers and fathers play with their young children have been remarked: Fathers' play is more physical, including more rough-and-tumble, while mothers' is more vocal. Yet here as elsewhere, when engaging in comparisons, one fastens on differences and forgets the similarities that greatly outnumber them. Thus, the responses of children to their fathers resemble those to their mothers.

As soon as investigators turned their attention to fathers, the larger picture came into view: Members of the family—mother, father, and siblings if present—not only interact with the youngest member of the family in their own individual fashion, but each separate interaction is affected by all the others. The social behavior of the infant and young child develops and is refined in a complex and multifaceted web of social relations.

Interestingly, attendance in day-care or nursery school settings does not seem to result in the loss of the emotional bond between children and their parents, which supports the contention that what is important is not the amount of time spent in interactions, but the nature of the interactions.

Interactions with Other Children

Even very young infants respond as socially to children as to their caretakers. It cannot be supposed that these very young children recognize other children as fellow creatures of their own small size and status. Rather, children being more lively than adults, they present more interesting stimuli, are more often playful, and may be more easily imitated.

Siblings, both older and younger, constitute a special class of children, distinguished by their familiarity and even more important by their contribution to the social web of the family. Although rivalry between siblings was vividly portrayed by David Levy in 1937, this does not tell the whole story. Naturalistic and laboratory studies, building on anecdotes, reveal many positive interactions. Older sib-

lings entertain, talk to, and play with their infant siblings. As the infants become toddlers, their siblings help and comfort them, and in turn the younger siblings find their older brothers and sisters attractive models, following where they go and imitating what they do.

Unrelated children also engage in congenial social interactions. Even infants smile and reach out to other infants, and older, but still young, children play together, with and without toys, and engage each other in true conversations. Early experience with other children of their own age, as well as with those older and younger, is often considered as important for young children's social development as association with adults. They learn the rules of a more egalitarian interaction, and by comparing themselves with others of their own age acquire knowledge of their own capabilities—knowledge that contributes to their developing concept of self.

Aggressive Behavior

Although the play groups of little children conjure up images of a melee of squalling, fighting children, the truth is quite otherwise. Conflicts do occur, usually over the possession of toys, but these are few relative to more positive interactions and are more often resolved by sociable acts than by force.

Development of Speech

Of the many activities composing the category of social behavior, speech occupies a preeminent position. Not only are newborns spoken to, but throughout the children's lives almost every subsequent contact with the parents, as well as with all other persons, is accompanied by speech. Even within the first months of life they vocalize in turn, setting the stage for a dialogue, a term that can well stand as a metaphor for all social interactions. While children are very young, adults carry the main burden of the conversation, marking their speech by a lively intonation, many repetitions, and much asking of questions. In turn, the vocalizations of the infant come to resemble the sounds and especially the intonations they hear.

By the end of the first year infants have acquired a word or two, and soon thereafter many words, as attentive bystanders label not only the objects and events in the environment but also the infants' own behavior. The adults' labeling of the infants' gestures—in particular, the infants' pointing to objects—plays an important part in establishing the meaning of their first words.

In studies of the semantic and syntactic properties of the child's speech, its social origins and pragmatic properties tend to be overlooked. The sine qua non of social behavior is communicating with others, and the modes of communicating are many, nonverbal and vocal as well as verbal. The child's use of the verbal mode, as of the other modes, originates in social interaction and, once acquired, plays a role of increasing importance in all social encounters.

Early Acquisition of Prosocial Behavior

During the second year of the child's life a number of behaviors such as comforting, sharing, and helping make their appearance and, with appreciation and reinforcement, develop into socially valued behaviors. These positive behaviors, being common, low-key, and undemanding, tend to go unremarked, posing as they do no problems for parents and teachers.

From an early age little children become emotionally upset at the distress of others and offer them sympathy by word and deed. They often spontaneously share their toys and possessions, and the objects they find, with other people and children, both familiar and unfamiliar. In extending such nurturant acts to both animate and inanimate objects, they creatively reenact the care they themselves had experienced at the hands of their parents.

Among the prosocial behaviors, obedience to the words of the parents deserves separate attention. Although here, too, more attention has been paid by parents and investigators to incidents when children do not obey, complying with verbal requests is the more common response. In fact, complying begins early and appears to develop without coercion. By the middle of the second year little children carry out many simple commands not only readily but often with pleasure, stemming apparently from their newfound ability to fit their behavior to the words of others.

Differences Between Boys and Girls

The sex of the child from birth is of paramount consequence to the beholder, if not yet to the child. No question is asked more consistently at the birth of a child than its sex.

Although many major attributes studies show no major differences in how parents rear their sons and daughters, nevertheless some do exist. For example, large differences fitting the culture's stereotypes were found in the type of toys parents provided for their young children. Parents of very young children profess to an intention to treat their children alike regardless of sex; they have been conditioned by a whole lifetime in a culture that has fairly definite ideas about sex-appropriate behavior. Furthermore, by 2 or 3 years of age children come to know, or at least to label, themselves as *boys* or *girls,* the first in a series of cognitive stages leading to gender identity sometime between 5 and 7 years of age.

Yet in the area of social behavior, no clear evidence has been presented of major differences in the interactions of boys and girls with parents, other adults, or children. Beyond infancy, as children come together in play groups and

nursery schools, physical aggression, although on the whole infrequent relative to peaceable interchanges, is seen more often in boys than in girls.

DEVIANCE

The study of deviance is based on two different points of view. The first has viewed deviance as an exceptional, but consistent, variation from statistical norms. In other words consistent performance, behavior, or cognition, which is an unusual occurrence in relation to the overall population, is considered deviant. This definition has been prominently used in the psychological study of deviance.

The second prominent position has seen deviance as defined by the occurrence of single critical events. The occurrence of unusual and high-intensity behaviors characterized by mental illness and violence exemplify this point of view. The critical event view of deviance is the basis of legal definitions of deviance.

Deviance has been the thrust of major aspects of personality theory, clinical psychology, and social psychology. The study of deviance can be classified into four major positions. The first posits that deviance is a function of internal factors. Deviance is seen as *differences among individuals.* The individual differences point of view suggests that individuals or groups of individuals possessing certain levels of characteristics are more likely to become deviant. Individual differences are further posited to be causally related to deviance.

A second major explanation of deviance posits *social structural differences* as major precursors. Officially codified forms of deviance tend to be disproportionately represented among the lower socioeconomic strata in our society. From a social structural point of view, it is suggested that differential access to legitimate opportunity, differential access to illegitimate opportunity, and alienation or enmity tend to be the critical ingredients causing deviance. From this point of view, deviance has both individual components that are a result of differential social structures, and environmental aspects.

A third major explanation of deviance takes an *interactionist point of view.* Formally entitled *labeling theory,* deviance is created by the reaction of critical individuals to a given act. Psychological disturbance, criminality, and underachievement are both formally and informally labeled as deviant. From the labeling perspective deviance is clearly an interaction between individual performances and society's reactions to those performances.

A fourth major point of view is that expressed by *learning theory.* Learning theory suggests that all actions, deviant and normal, are learned according to the laws of modeling, reinforcement, and punishment. Those individuals who display deviant behavioral patterns have received differential reward for such actions. From the learning theory point of view there is no inherent difference between deviant and normal behavior. Criminal behavior, abnormal behavior, and learning disabilities are learned.

DIAGNOSIS

Diagnosis is the act of identifying and naming a disorder or disease by using an agreed-upon system of categorization. In North America, mental and emotional syndromes are currently diagnosed according to the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV;* American Psychiatric Association [ApA], 1994).

Roots of the *DSM-IV*

The roots of the *DSM-IV* extend back to nineteenth-century German psychiatrist Emil Kraepelin, who believed strongly in the detailed medical and psychiatric histories of patients, emphasized thorough observation of signs and symptoms, and considered some disorders, including prominently the psychoses, to be diseases of the brain. Despite a few earlier unsuccessful efforts, it was not until the end of World War II that representatives of the War Department, the Veterans Administration, and the civilian psychiatric community in the United States began discussing the creation of a national nomenclature that could simultaneously serve their diverse needs. The result was a syndromally based nomenclature, the *DSM-I* (ApA, 1952).

The DSM-I *and the* DSM-II

The *DSM-I* was designed to permit mental health professionals across the United States to use a common diagnostic language for the first time. Notwithstanding the *DSM-I* and its similar successor, the *DSM-II* (ApA, 1968), had serious deficiencies. Because they provided only brief descriptions of each disorder, the reliability of resultant diagnoses was low. Moreover, syndrome descriptions were not empirically based and often failed to correspond to the clinical experience of those working in clinical settings.

The DSM-III

The roots of the *DSM-III* lie in (1) late 1960s research by psychiatrist R. L. Spitzer at the New York State Psychiatric Institute that led to the development of a series of structured diagnostic interviews (e.g., Spitzer, Fleiss, Endicott, & Cohen, 1967) designed to gather the data on signs and symptoms on which an empirically based nomenclature could be built, (2) an influential article by Feighner and colleagues (1972) that proposed explicit, empirically derived diagnostic criteria for 16 major diagnostic categories, and (3) publication of the *Research Diagnostic Criteria* (*RDC;* Spitzer, Endicott, & Robins, 1975), which allowed empirical testing of the reliability of the Feighner criteria.

The *DSM-III* (ApA, 1980) represented a breakthrough in efforts to heighten the reliability and, to a lesser extent, the validity and utility of syndromal diagnosis. The instrument's diagnostic criteria, and those of its successors, the *DSM-III-R* (ApA, 1987) and the *DSM-IV* (ApA, 1994), represent its major departure from its predecessors. Modeled after the *RDC,* the diagnostic criteria organized each syndrome's signs and symptoms in a consistent format. As a result, the reliability of *DSM-III* diagnoses selectively improved.

The clinical utility of the *DSM-III* also improved. The *DSM-III* text, and those of its successors, contained several times as many pages and words as its predecessors, permitting far greater explication of each of the more than 300 sets of operational criteria (more than 3 times as many as its predecessors), as well as information on associated features, age of onset, course, nature and extent of impairment, complications, predisposing features, prevalence, sex ratio, familiar pattern, and differential diagnostic issues.

The *DSM-III* also introduced the multiaxial system, which assesses each patient along five axes, rather than only one, as in the *DSM-I* and the *DSM-II.* Not only are patients assessed on psychopathology on Axes I and II, but also on the physical conditions which might have contributed to their psychopathology (Axis III), the severity of the psychological stressors to which the patient was exposed (Axis IV), and the patient's highest level of adaptive functioning during the preceding year (Axis V).

The DSM-IV

A principal goal of the *DSM-IV* process was to create a nomenclature based even more than the *DSM-III* on empirical research. Thirteen work groups, one for each major diagnostic grouping, first undertook systematic literature reviews designed to address unresolved diagnostic questions. When literature reviews failed to resolve questions, the work groups sought to locate clinical data sets that would do so; 40 analyses of existing patient data sets were ultimately carried out. The work groups also designed and carried out extensive field trials to generate new clinical data; 12 large-scale field trials at more than 70 sites worldwide, involving more than 7,000 participants, were completed.

Reliability and Validity of *DSM-IV* Diagnoses

Most data reported to date on the reliability and validity of *DSM-IV* categories have come from the field trials. They suggest modest increments in the reliability of a few diagnostic categories (e.g., Oppositional Defiant Disorder and Conduct Disorder in children and adolescents, Substance Abuse and Dependence) and in validity (e.g., Autistic Disorder; Oppositional Defiant Disorder in childhood and adolescence). However, little progress was made in addressing the substantial reliability problems of the Personality Disorders, the Sleep Disorders, the disorders of childhood and adolescence, and some of the disorders within the schizophrenic spectrum.

Criticisms of the *DSM-IV*

In a response to criticisms that professional issues overshadowed scientific ones in the creation of the *DSM-IV* (e.g., Caplan, 1991), Widiger and Trull (1993) admitted that the *DSM-IV* Task Force was sensitive to a variety of professional issues. Nonetheless, they see it as primarily an empirically driven instrument. As well, Guze expressed concern in 1995 that many *DSM-IV* diagnostic conditions continue to fail to meet Robins and Guze's (1970) criteria for diagnostic validity; this is a theme others (e.g., Kirk & Kutchins, 1992) have also sounded.

Comorbidity of Diagnoses

There is substantial overlap among disorders in the *DSM-IV.* With others, Klein and Riso (1993) have asked whether these disorders represent discrete, "natural" classes or artificial categories created by the establishment of arbitrary cutoffs on a continuum. In a report from the National Comorbidity Survey (NCS), Blazer and his colleagues (Blazer, Kessler, McGonagle, & Swartz, 1994) confirmed the high rates of co-occurrence between major depression and a range of other psychiatric disorders. Kessler and colleagues (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995), in a second NCS article, reported that Posttraumatic Stress Disorder is strongly comorbid with other lifetime *DSM-III-R* disorders in both men and women, especially the affective disorders, the Anxiety Disorders, and the Substance Use Disorders. Magee and his colleagues (Magee, Eaton, Wittchen, McGonagle, & Kessler, 1996) report that lifetime phobias are highly comorbid with each other, with other Anxiety Disorders, and with affective disorders.

The Categorical Versus Dimensional Debate

Categorical versus dimensional classification first became a matter of concern when the *DSM-III* tripled the number of diagnoses described by its predecessors, thereby raising the question of boundaries between old and new diagnostic entities. As diagnoses proliferated, the frequency of comor-

bidity increased, causing clinicians to ask whether comorbidity represents the co-occurrence of two or more mental disorders or a single disorder that has simply been labeled in different ways. As a consequence, the advantages and disadvantages of dimensional and categorical approaches to personality and diagnosis are now being explored extensively (e.g., Widiger, 1997). The focus of these efforts is on the Personality Disorders, where symptom overlap is greatest.

DIAGNOSTIC INTERVIEW SCHEDULE FOR *DSM-IV (DIS-IV)*

The ability to diagnose psychiatric disorders accurately has improved dramatically over the last 20 years. Structured interviews have played a major role in this advancement, and the *Diagnostic Interview Schedule for DSM-IV* (*DIS-IV;* Robins, Cottler, Bucholz, Compton, North, & Rourke, 1999) is among the most prominent and popular of these instruments.

Overview and History

The *DIS-IV* is a fully structured interview designed to assess the presence or absence of major psychiatric disorders. It was crafted to be administered in a reliable and valid fashion by nonclinician interviewers. Computerized administration of the *DIS-IV* (*C-DIS*) is standard. Computerized administration may be interviewer-administered or self-administered. In both formats, the exact wording of all questions and probes are presented to the respondent in a standardized order on a computer screen, and rephrasing of questions is discouraged, although *DIS* interviewers can repeat questions as necessary to ensure that they are understood by the respondent. All questions are written to be closed-ended, and replies are coded with a forced choice yes or no format, which eliminates the need for clinical judgment to rate responses. The *DIS* gathers all necessary information about the subject from the subject; collateral sources of information are not used. The *DIS* is self-contained and covers all necessary symptoms to make many *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (*DSM-IV*) diagnoses (American Psychiatric Association, 1994). Responses are directly entered into a database dur-

ing the interview, and the diagnosis is made according to the explicit rules of the *DSM-IV* diagnostic system.

In 1978, development of the original *DIS* was begun by researchers at the Washington University Department of Psychiatry in St. Louis at the request of the National Institute of Mental Health (NIMH). At that time, the NIMH Division of Biometry and Epidemiology was planning a set of large-scale, multicenter epidemiological investigations of mental illness in the general adult population in the United States as part of its Epidemiological Catchment Area Program. Variables under study included incidence and prevalence of many psychiatric disorders and utilization profiles of health and mental health services. With this grand purpose in mind, development of a structured interview that could be administered by nonclinicians was imperative due to the prohibitive cost of using professional clinicians as interviewers. As a result, the *DIS* was designed as a fully structured diagnostic interview that minimizes the amount of clinical experience required to administer it.

Since its initial development, the *DIS* has undergone several major revisions. For example, the original *DIS* (Robins, Helzer, Croughan, & Ratcliff, 1981) covered criteria for only 31 *DSM-III* diagnoses, with later versions adding more disorders. Another refinement was the addition of a comprehensive set of training materials including training videotapes and extensive training courses. Perhaps most importantly, *DIS* questions and diagnostic algorithms were revamped to match new criteria in *DSM-III-R* (called Version DIS-III-R; Robins, Helzer, Cottler, & Goldring, 1989), and most recently in *DSM-IV* (ApA, 1994).

Features of the *DIS*

Since the *DIS* was designed for epidemiological research with normative samples, interviewers do not elicit a presenting problem from the respondent, as would be typical in unstructured clinical interviews. Rather, *DIS* interviews begin by asking questions about symptoms in a standardized order. Like other structured interviews, the *DIS* has sections that cover different disorders. Each diagnostic section is independent, except where one diagnosis preempts another. Once a symptom is reported to be present, further closed-ended questions are pursued to assess additional diagnostically relevant information such as severity, frequency, time frame, and possibility of organic etiology of the symptom. The *DIS* includes a set of core questions that are asked of each respondent. Core questions are followed by contingent questions that are administered only if the preceding core question is endorsed. *DIS* interviewers utilize a probe flow chart that indicates which probes to use in which circumstances.

For each symptom, the respondent is asked to state whether it has ever been present and how recently. All data about presence or absence of symptoms and time frames of occurrence are coded and entered into the computer. Consistent with its use of nonclinician interviewers, the diagnostic output of the *DIS* is generated by a computer program which analyzes data from the completed interview. The output provides estimates of prevalence for two time periods: current and lifetime.

Due to its highly specified format, full administration of the *DIS-IV* interview typically takes 75–150 minutes. To shorten administration time, the modular format makes it possible to drop evaluation of disorders that are not of interest in a particular study. Another option is to drop further questioning for a particular disorder once it is clear that the threshold number of symptoms needed for diagnosis will not be met. Modules can be dropped, shortened, or asked in full depending on the specific research needs.

Although designed for use by nonclinician administrators, training for competent administration of the *DIS* is intensive. Trainees typically attend a 1-week training program at Washington University during which they review the *DIS* manual, listen to didactic presentations about the structure and conventions of the *DIS,* view videotaped vignettes, complete workbook exercises, and conduct several practice interviews followed by feedback and review. Additional supervised practice is also recommended.

The psychometric properties of the original *DIS* and its revisions have been evaluated in numerous investigations, with encouraging results. The interested reader is referred to Segal and Coolidge (2003) for a full discussion of reliability and validity data for the *DIS*. Overall, the *DIS* has proven to be a popular and useful diagnostic assessment tool, especially for large-scale epidemiological research. The *DIS* has been translated into over a dozen languages. It is used in many countries for epidemiological research and served as the basis for the Composite International Diagnostic Interview used by the World Health Organization. Presently, the *DIS-IV* is the only well-validated case finding strategy that can make *DSM-IV* diagnoses in large-scale epidemiological research. Like earlier versions, the *DIS-IV* can be expected to enjoy widespread application in psychiatric research, service, and training for many years to come. Given the history of the *DIS,* its continued evolution will likely make it a popular and effective instrument for psychiatric diagnosis in the twenty-first century. For further information, see the *DIS* web site at http://epi.wustl.edu.

DICTIONARY OF OCCUPATIONAL TITLES

First produced by the U.S. Department of Labor in 1939, the *Dictionary of Occupational Titles* (*DOT*) provides standardized occupational information useful to individuals and professionals in the job-seeking process. The *DOT* represents an extremely wide variety of occupational activities related to the full range of service provided by the U.S. employment services.

Among the items included are descriptions of more than 20,000 occupations, covering almost all jobs in the U.S. economy. Because it groups occupations into a systematic classification structure based on how jobs are related with respect to their tasks and requirements, it is extremely useful as a job placement tool. It enhances the ability of the personnel worker to match worker skills with job requirements.

Occupational titles are arranged by groups, by industries, and alphabetically. Definitions are organized into six basic components: occupational code number, occupational title, industry designation, any alternate titles, the definition itself, and any undefined related title.

The occupational code is a nine-digit number. The first three digits identify an occupational group. The first digit identifies a broad occupational category; the second, some subdivision within the category; and the third, the occupation within the broader subdivision.

The second three digits of the code describe worker function. These are defined in terms of data, which are the fourth digit; people, the fifth digit; and things, the sixth digit. Together, they describe the degree of involvement that the job has with data, people, and things.

The last set of three digits differentiates a particular occupation from any other occupations that might have the same first six digits. No two occupations, therefore, can have the same nine digits.

The total system has many very useful features. The *DOT* can identify, for example, tasks that workers might have to perform in a particular occupation, the kinds of machines or tools that might be used, the amount of independent judgment that a worker might have to exercise in the performance of a job, and the setting in which the work might be done. In addition, each occupation is described in terms of its exertional requirements and skill level, as well as the level of proficiency in general level of intelligence, verbal, and computations skills it requires.

This system is subject to replacement at some future date by a system called *O-Net*.

DIFFERENTIAL PSYCHOLOGY

This branch of psychology is concerned with the nature and origins of individual and group differences in behavior. Measurement of such differences has produced an extensive body of descriptive data of considerable scientific and practical interest in its own right. More basically, however, differential psychology represents one avenue to an understanding of behavior; its characteristic approach is through the comparative analysis of behavior under varying biological and environmental conditions. By relating observed behavioral differences to known concomitant circumstances, it is possible to investigate the relative contributions of different variables to behavior development.

As an organized field of scientific endeavor, differential psychology began to take shape during the last quarter of the nineteenth century. Francis Galton contributed significantly to the investigation of individual differences, devising tests for the measurement of sensorimotor and other simple functions, gathering data in a variety of settings, and developing appropriate statistical techniques for data analysis. James McKeen Cattell, an American student of Wilhelm Wundt, extended Galton's work in test development and incorporated this approach in the emerging field of experimental psychology.

The first systematic description of the aims, scope, and methods of a psychology of individual differences appeared in an 1895 article by Alfred Binet and Victor Henri, "La psychologie individuelle" (Individual psychology). A fuller development of relevant topics, together with summaries of available findings, was provided in 1900 by William Stern. The term *differential psychology,* first introduced in the subtitle of his book, was incorporated formally in the revised and enlarged later editions, whose title reads, *Die Differentielle Psychologie in Ihren Methodischen Grundlagen*

(Methodological Foundations of Differential Psychology). Subsequent progress in the study of individual and group differences parallels closely the growth of psychological testing, as well as advances in related fields, notably genetics, developmental psychology, and cross-cultural psychology, all of which have made significant contributions to the methodology, data, and concepts of differential psychology.

Scope and Distribution of Individual Differences

Individual differences in behavioral characteristics are not limited to the human species, but occur throughout the animal scale. Investigations of animal behavior, from unicellular organisms to anthropoid apes, reveal wide individual differences in learning, motivation, emotionality, and other measurable traits. So large are these differences that the distributions of individual performance overlap even when widely separated species are compared.

Although in popular descriptions persons are often placed into distinct categories, such as bright or dull and excitable or calm, actual measurement of any psychological trait shows individuals to vary in degree along a continuous scale. In most traits, the distributions approximate the bell-shaped normal probability curve, with the greatest clustering of cases near the center of the range and a gradual decrease in numbers as the extremes are approached. First derived by mathematicians in their study of probability, the normal curve is obtained whenever the measured variable depends on a very large number of independent and equally weighted factors. Because of the extremely large number of hereditary and environmental factors that contribute to the development of most psychological traits, the normal curve is generally accepted as the most appropriate model for trait distribution, and psychological tests are generally constructed so as to conform to this model.

Heredity and Environment

Concepts

The origins of individual differences in behavioral characteristics are to be found in the innumerable interactions between heredity and environment that occur throughout one's life span. An individual's heredity consists of the genes received from each parent at conception. Genes are units of complex chemical substances transmitted on the chromosomes of the ovum and spermatozoon that unite to form the new organism. If there is a chemical deficiency or imbalance in one of these genes, a seriously defective organism may result, with physical pathology and severe mental retardation, as in phenylketonuria (PKU). Except for such pathological deviates, however, heredity sets broad limits to behavior development, and the limits are broader in the human than in lower species. Within these limits, what individuals actually become depends on their environment.

The environment comprises the sum total of stimuli to which the individual responds from conception to death. It covers a vast multiplicity of agents, ranging from air and food to the intellectual and emotional climate of home and community and the beliefs and attitudes of one's associates. Environmental influences begin to operate before birth. Nutritional deficiencies, toxins, and other chemical or physical conditions of the prenatal environment may have profound and lasting effects on both physical and mental development. Such terms as *inborn, innate,* and *congenital* are often misused with the false implication that all characteristics present at birth are hereditary. Another common confusion is the difference between organic and hereditary conditions. Mental retardation resulting from early brain injury, for instance, may be properly said to have an organic but not a hereditary origin.

Methodology

The many methods used to investigate the operation of hereditary and environmental influences in behavior development may be subsumed under three major approaches: *selective breeding, experiential control,* and *statistical studies of family resemblances.* Selective breeding for behavioral characteristics has been successfully applied to several species. From a single initial group of rats, for example, it proved possible to breed two strains comprising good and poor maze learners, respectively. That the two strains did not differ in general learning capacity, however, was demonstrated by the finding that both strains performed equally well in other learning problems. Still another study of these selectively bred strains provided a clear example of the interaction of heredity and environment. When reared in restrictive environments, both strains performed almost as poorly as did the genetically "dull" rats reared in a natural environment. In contrast, an enriched environment, providing a variety of stimulation and opportunities for motor activity, improved the performance of the "dull" strain, both groups now performing at about the level of the "bright" rats in a natural environment.

Later selective breeding experiments extended these procedures to other species and other types of behavior. Of particular significance was the development of techniques for measuring individual differences in behavior among such organisms as the fruit fly *Drosophila.* It thus became possible to capitalize on the mass of available genetic knowledge regarding the morphology of *Drosophila,* as well as on such other advantages as the short time span between generations and the abundance of progeny. Through these procedures, a strain of fruit flies was bred that would fly *toward* a source of light and another that would fly *away* from it.

A second approach to the study of heredity and environment is concerned with the behavioral effects of systematic, controlled variations in experience. Experimental investigations of this question either provide special training or prevent the normal exercise of a particular function. This method has frequently been followed with animals to study a wide variety of activities, ranging from the swimming of tadpoles and the singing of birds to sexual behavior and care of the young. Significant effects of such experiential manipulations have been reported for nearly all types of behavior, including perceptual, motor, learning, emotional, and social reactions. Through such experiments, activities formerly regarded as completely unlearned or "instinctive," such as nest building and grooming of the young by rats, have been shown to depend on the animal's prior experiences. Even when the animal has no opportunity to learn the specific activity in question, its behavior may be influenced by the exercise of other related functions.

In studies of infants and young children, one group of experiments utilized the method of cotwin control, in which one identical twin is given intensive training in, for example, stair climbing, while the other serves as the control. The results generally show that, if training is introduced when the child is physically ready for it, progress will be faster than if training is given earlier. Other studies have compared the development of children reared in experientially restricted environments, such as orphanages, with that of children reared in more stimulating environments. Marked differences have been found as a function of the amount of adult contact as well as the extent of physical stimulation and opportunities for motor activity. There is evidence, however, that appropriate educational programs, particularly when initiated in early childhood, may counteract the detrimental effects of such deprived environments on intellectual development.

The third major approach is based on statistical analyses of familial resemblance. Similarity of performance on both aptitude and personality tests have been investigated for parents and children, siblings, and both fraternal and identical twin pairs. In general, the closer the hereditary relation, the more similar the test scores. On most intelligence tests, for instance, identical twin correlations are close to .90, being nearly as high as the correlations between test and retest scores of the same persons. Fraternal twin correlations cluster around 0.70; those between siblings cluster around 0.50, as do those between parents and children. It should be noted, however, that a family is a cultural as well as a biological unit. In general, the more closely two persons are related by heredity, the greater will be the similarity of their environments and the extent of their influence on each other. Special studies of foster children and identical twins reared apart permit some separation of hereditary and environmental contributions, but several uncontrolled conditions in these studies preclude definitive conclusions.

Nature of Intelligence

Composition

Intelligence has been commonly identified with the intelligence quotient (IQ) obtained on a standardized intelligence test. Such tests reflect at least partly the concept of intelligence prevalent in the culture in which they were developed. Modern intelligence testing originated with Alfred Binet's development of a test to assess intellectual retardation among schoolchildren. Intelligence tests have frequently been validated against such academic criteria as school grades, teachers' ratings of intelligence, promotion and graduation data, and amount of schooling completed. In content, most intelligence tests are predominantly verbal, with some coverage of arithmetic skills and quantitative reasoning. Different intelligent tests, however, may sample somewhat different combinations of abilities. Nonlanguage and performance tests, for instance, often make much heavier demands on spatial visualization, perceptual speed and accuracy, and nonverbal reasoning than do the usual verbal-type tests.

With the increasing participation of psychologists in vocational counseling and personnel selection came the realization that supplementary tests were needed to measure aptitudes not covered by traditional intelligence tests. As a result, so-called special aptitude tests were developed for mechanical, clerical, and other occupationally useful abilities. At the same time, basic research on the nature of intelligence was being conducted by the techniques of factor analysis. Essentially, these techniques involve statistical analyses of the intercorrelations among test scores in the effort to identify the smallest number of independent factors that can account for the intercorrelations. Among the aptitudes, or factors, thus identified are verbal comprehension, word fluency, arithmetic skills, quantitative reasoning, perceptual speed, spatial visualization, and mechanical comprehension. Through factor analysis, the functions measured by intelligence tests were themselves sorted into relatively independent verbal and numerical aptitudes. These aptitudes, in combination with those underlying special aptitude tests, now provide a more comprehensive picture of human abilities. Several of these abilities are incorporated in what are generally designated multiple-aptitude batteries.

From another angle, the increasing accumulation of data from cross-cultural research indicated that intelligence can have different meanings in different cultures. Both traits constitute intelligence, and the relative level of development of these traits reflects the demands and the contingent reinforcements provided by the cultures in which people function. Investigations in preliterate cultures show that those members who have been exposed to a substantial amount of Western-type schooling are more likely to respond in terms of abstract concepts and are less context-bound than are their more traditionally reared age peers. Within a cross-cultural frame of reference, available intelligence tests can be most appropriately de-

scribed as measures of academic intelligence or scholastic aptitude. These skills represent a limited segment of intelligence, but a segment that is broadly applicable and widely demanded in modern, technologically advanced societies. Within such societies, academic intelligence correlates substantially, not only with school achievement, but also with achievement in most occupations and in other major societal activities.

The intellectual functions tapped by traditional intelligence tests have also been investigated by cognitive psychologists within the framework of information processing and computer simulation of human thinking. Although this area of research is still in its early stages, it is contributing to an understanding of what intelligence tests measure by focusing attention on processes rather than end-products in problem solving. *What* does the examinee do when responding to test items? Analyzing intelligence test performance in terms of elementary component processes may eventually help to identify each person's sources of strength and weakness. Such analysis should enhance the diagnostic use of tests and facilitate the tailoring of training programs to fit each individual's needs.

Life-Span Development

Longitudinal studies of age changes with respect to performance on traditional intelligence tests reveal a slow rise in infancy, followed by more rapid progress and eventual slowing down as maturity is approached. It should be noted, however, that the trait cluster measured by intelligence tests varies with age. In infancy, the IQ is based largely on sensorimotor development, whereas in childhood, it depends increasingly on verbal and other abstract functions. During the period of uniform formal schooling, the content of intelligence tests closely reflects what is learned in school. Later, changing patterns of intellectual development associated with progressive educational and occupational specialization may not be fully identified through available intelligence tests; they may require a broader spectrum of tests and other assessment procedures.

Average performance on traditional intelligence tests shows continuing improvement with age through the 20s. Among high-scoring groups, especially college graduates and those engaged in intellectually demanding occupations, such improvements may continue throughout life. In more nearly average samples, tested abilities tend to decline beyond the 30s, the drop being largest in tasks involving speed, visual perception, and abstract spatial relations. In cross-sectional studies, which use different samples at different age levels, age differences are likely to be confounded with cultural changes in the population because of lack of comparability of the different age groups in amount of education and other changing life conditions. Well-designed longitudinal studies of adults indicate that the decline attributable to age is much smaller than are the differences attributable to educational and cultural changes over time.

Intellectual Deviates

The mentally retarded and the gifted represent the lower and upper extremes of the distribution of intelligence. Because the distribution is continuous, there is no sharp separation between these groups and the norm. In terms of intelligence test performance, mental retardation is customarily identified with IQs below 70, representing about 2–3% of the general population. Decisions regarding the disposition and treatment of individual cases are based not only on the IQ but also on a comprehensive study of the individual's intellectual development, educational history, social competence, physical condition, and familial situation. Although a few rare forms of mental retardation result from defective genes, the large majority of cases can be traced to environmental conditions operating before or after birth and including both physical and psychological influences.

At the other end of the scale, the intellectually gifted have been investigated by various procedures and from several points of view. In a major, long-term project conducted by Lewis M. Terman and his associates at Stanford University, approximately 1,000 children with Stanford-Binet IQs of 140 or higher were intensively examined and subsequently followed up at several life stages. IQs as high as these are found in slightly more than 1% of the general population. The results of the Stanford study, which have been corroborated in several investigations conducted elsewhere, revealed the gifted child as typically successful in school, healthy, emotionally stable, and having a wide range of interests. As they grew into maturity, these gifted children on the whole maintained their superiority in adult achievements.

The concept of intelligence was thereby broadened to include several creative abilities, such as ideational fluency and originality. Motivation, interests, and other personality variables were also found to play important parts in creative achievement, as did the psychological climate of the environment in which the individual was reared and in which he or she functioned as an adult.

Group Differences

Sex Differences

The investigation of any group differences in behavioral characteristics presents several methodological and interpretive problems. In group comparisons, individual differences *within* each group have proved far greater than average differences *between* groups. The distributions of different groups overlap to a marked extent. Even when there are large, statistically significant differences between the mean scores of two groups, individuals can be found in the lower-scoring group who outperform individuals in the higher-scoring group. It follows that one's group membership is not a dependable indicator of one's standing in psychological traits.

Another problem arises from the use of unrepresentative samples in which selective factors may have operated differentially for the populations under investigation. Insofar as more boys than girls may drop out of school, for example, a comparison of the intelligence test scores of high school boys and girls will show a mean difference in favor of boys. This difference would disappear if we were to include dropouts, who tend to score toward the low end of the distribution. A similar interpretive error in the opposite direction is illustrated by surveys of institutionalized mental retardates, which have generally shown an excess of males. Although once regarded as evidence for the higher incidence of mental retardation among males, these findings were later traced to selective admission policies. For various social and economic reasons, mentally retarded females were more likely to remain in the community than were males of the same intellectual levels.

The use of total scores on intelligence tests may also be misleading in group comparisons. In the construction of several intelligence tests, such as the Stanford-Binet, sex differences were ruled out by omitting or balancing out items that favored either sex. Even when this practice is not followed in selecting items, a composite score on a heterogeneous test may obscure existing group differences in specific abilities.

Psychological test surveys have demonstrated significant mean differences between the sexes in a number of aptitudes and personality traits. Females as a group excel in finger dexterity, perceptual speed and accuracy, verbal fluency and other tasks involving the mechanics of language, and rote memory for most types of content. Males excel in speed and coordination of gross bodily movements, spatial orientation, mechanical comprehension, and mathematical reasoning. Among personality differences, one of the best established is the greater aggression of the male. This difference is manifested early in life and is found consistently across cultural groups. It has also been observed in animals, notably subhuman primates and most other mammalian species. Several investigations indicated a stronger achievement drive in the male, but this difference was subsequently found to vary with the conditions under which it was assessed; the results may reflect in part the extent to which the context is task-oriented or person-oriented. There is considerable evidence that females exhibit a stronger social orientation and desire for social approval than do males, as well as less self-confidence and a higher level of anxiety in various situations.

Most investigations of sex differences yield only descriptive data about existing differences within a given culture. The origins of such differences must be sought in the complex interactions of biological and cultural factors. From a biological viewpoint, the different roles men and women play in the reproductive function undoubtedly contribute to sex differentiation in psychological development. The long period of childbearing and child rearing, which falls biologically on the female, has had far-reaching effects on sex differences in interests, attitudes, emotional traits, occupational goals, and achievement. Sex differences in aggression are associated with the greater body size, muscular strength, and physical endurance of the male. There is also considerable experimental evidence that aggressive behavior is related to the level of sex hormones. Another significant sex difference is to be found in the developmental acceleration of girls. Not only do girls reach puberty earlier than boys, but throughout childhood they are also further advanced toward their own adult status in all physical traits. In infancy, the developmental acceleration of girls may be an important factor in their more rapid acquisition of language and may give them a head start in verbal development as a whole.

The contributions of culture can be readily illustrated. Although living in the same homes, girls and boys in most societies are reared in different subcultures. In countless ways they receive differential treatment from parents, other adults, and age peers. The personalities of mother and father are themselves important factors in the child's developing concept of sex roles, providing models of what is expected of each sex in the particular culture. Sex-role stereotypes are likely to influence sex differentiation in motivation, interests, and attitudes. There is also some evidence that performance on cognitive tasks, such as problem solving and achievement tests in reading and arithmetic, is significantly related to the degree of individuals' sex-role identification and their own evaluation of the sex-appropriateness of various activities. Most of the descriptive data regarding sex differences in psychological traits were gathered in the United States and other contemporary Western nations prior to the advent of the current feminist movement. The educational, occupational, and social changes promoted by that movement may be reflected in changes in the relative development of males and females in both cognitive and noncognitive areas.

Racial and Cultural Differences

Race is a biological concept referring to subdivisions of a species. It corresponds to such classifications as breed, stock, or strain in animals. Human races are formed when a group becomes relatively isolated, through either geographic or social barriers, so that mating among its members is more frequent than mating with outsiders. Over many generations, this process produces populations that differ in the relative frequency of certain genes. Because these differences are relative and not absolute, however, any racial group exhibits some variation in hereditary racial characteristics and overlaps with other populations in such characteristics. For this reason, the concept of race can be properly applied to populations, but not to individuals.

When persons are classified according to such categories as socioeconomic level, nationality, or ethnic identity, significant group differences are often found in child-rearing

practices, sexual behavior, emotional responses, interests, and attitudes, as well as in performance on many aptitude tests. In all such comparisons, the direction and amount of group difference depend on the particular trait that is investigated. Because each culture or subculture fosters the development of its own characteristic pattern of aptitudes and personality traits, comparisons in terms of such global measures as IQ or general emotional adjustment can have little meaning.

Isolation of groups leads to cultural as well as racial differentiation. Hence, it is difficult to disentangle the contributions of biological and cultural factors to race differences in psychological traits. Test performance of hybrid, or racially mixed, groups has been investigated for this purpose. It has been argued that, if one race is intellectually superior to another because of genetic factors, the hybrid offspring of both races should be intermediate in intelligence. As commonly tested, this hypothesis is questionable because it assumes complete linkage between the genes determining skin color or other racial indexes and the genes determining intelligence. With incomplete linkage, the correlation between racial characteristics and intelligence would disappear within a few generations of crossbreeding. The results are further complicated by the fact that race mixture is usually selective within either or both races, as well as by the tendency toward greater cultural assimilation of hybrids into the majority population. In groups that were fairly homogeneous in their assimilation of the majority culture, and in which individuals were classified according to ancestry records rather than appearance, the correlation between test scores and extent of race mixture was negligible.

Another approach is concerned with changes in the comparative test performance of racial groups with age. Studies of Black infants and preschool children in the United States, for example, revealed little or no retardation in terms of White norms. Tests administered to schoolchildren in the same regions and time periods, however, showed significant mean retardation that increased with age. These findings are similar to those obtained with various other groups reared in educational and culturally restricted environments. The age decrement has been attributed to the cumulative effects of experiential limitations and to the increasing inadequacy of such environments to meet the expanding intellectual needs of the growing child. From a broader viewpoint, such an age decrement in relation to test norms may be said to occur when a test assesses cognitive functions not fostered in a particular culture or subculture.

A third approach compares samples of the same race reared in different environments. In general, such studies have yielded larger differences in test performance among subgroups of a single race living in different milieus than among different racial groups living under more nearly similar conditions. That the regional differences found within a racial population are associated with cultural differences rather than with selective migration has been demonstrated in several studies.

Studies of so-called equated groups of different races generally show substantial reduction in mean IQ differences, although some difference remains. Such studies are subject to several methodological difficulties. One is statistical regression toward the mean, which occurs whenever a matched-sample experimental design is employed with populations that differ in the equating variable, such as socioeconomic level. The effect of this procedure is to produce mean differences in, for example, IQ in the samples chosen, simply as a statistical artifact of the selection procedure. Another difficulty arises from the use of very broad categories for classifying such variables as socioeconomic and educational levels. With broad categories, it is likely that the individuals from one population cluster at the low end *within* each category, whereas those in the other population cluster at the high end, even though they were selected so that the total number within each category was the same.

A related difficulty pertains to the use of such traditional equating variables as parental occupation and education, whose relation to the child's psychological development may be too indirect and remote. There is an increasing tendency to construct home environment scales that are more detailed and more immediately relevant to the development of specified traits, such as scholastic aptitude. Use of such scales in comparative studies of Black and White preschool children and high school students yielded promising evidence of the dependence of group differences in intellectual development on the relevant characteristics of home environments.

In light of available knowledge, only a few conclusions can be drawn with confidence. First, no biological basis has as yet been clearly identified for any existing psychological race difference. Second, there is considerable evidence, from both racial studies and other types of investigations in differential psychology, showing the part played by cultural factors in producing the sort of behavioral differences commonly found among racial groups. Finally, in all psychological traits, the range of individual differences within each race is far larger than the mean difference between races.

With regard to group differences in general, we can say that empirically established *group differences* become *group stereotypes* when (1) mean differences are ascribed indiscriminately to all individuals within the group, and (2) the observed differences are assumed to be rigidly fixed, unchangeable, and hereditary.

DIGESTIVE SYSTEM

The *digestive system* refers to those organs involved in the process of breaking down ingested food into molecules that are used to nourish the body. The digestive system includes all portions of the gastrointestinal tract—mouth, esophagus, stomach, small intestine, large intestine, rectum, and anus—and the organs that secrete chemical juices necessary for the digestive process: salivary glands, liver, gall bladder, and pancreas.

In the mouth, the food is chewed into relatively small particles and mixed with saliva, which contains ptyalin, an enzyme which converts some starches to sugar. After the food passes through the esophagus and into the stomach, it is vigorously mixed with hydrochloric acid and the enzyme pepsin. This initiates the digestion of proteins. The food, which is now a thick liquid, is called *chyme*. When the particle size and chemical nature of the chyme is at the appropriate level, a sphincter opens, allowing the chyme to pass into the small intestine. In the small intestine, pancreatic juice containing the enzymes trypsin, amylase, and lipase continue the breakdown of the partially digested food. The complete digestive process is aided by additional secretions in the small intestine including bile, which is produced in the liver and stored in the gall bladder.

When the food is completely digested, it is absorbed in the walls of the small intestine and carried by the circulatory system to all parts of the body. The role of the large intestine is to store nondigestible waste products and to absorb small amounts of water and minerals.

The psychophysiology of the gastrointestinal (GI) system is a relatively unexplored area. We note the 1943 landmark work of Wolf and Wolff in which they described the secretory and motility changes of their fistulated subject to various stress situations, and the very recent work of GI psychophysiologists who have demonstrated that behavioral stressors, which influence autonomic and cardiovascular reactivity, also influence gastric activity, but there were few studies reported in between. However, the paucity of psychophysiology research on the GI system is not so surprising when we consider the instrumentation and measurement problems of obtaining data from far inside this constantly changing many-meter-long system.

As a consequence of these problems, no psychophysiological studies of absorption are known to the author, and few studies of gastric acid secretion have been conducted by psychophysiologists. However, several studies of motor activity have been conducted, particularly in the more easily accessible two ends of the GI tract, the esophagus and rectum, and also in the stomach. An increasing number of studies have recently been published by psychophysiologists in which the motor activity of the stomach was measured with the noninvasive method of electrogastrography.

Electrogastrography refers to the recording of electrogastrograms (EGGs). Electrogastrograms reflect gastric myoelectrical activity as it is recorded from the abdominal surface with cutaneous electrodes. EGGs are sinusoidal waves recurring at a rate of 3 cycles per minute (cpm) in healthy humans. This predominant frequency is usually discernable by visual inspection of the signal, but computer analysis is essential for quantitative study of EGG recordings. The stomach is also the source of abnormally fast or slow usually dysrhythmic myoelectrical signals, the tachygastrias (4–10 cpm) and bradygastrias (1–2.5 cpm). Acute or chronic shifts from normal 3 cpm EGG signals to the gastric dysrhythmias are associated with a variety of clinical syndromes and symptoms, particularly nausea. In contrast to the abnormalities in frequency such as the gastric dysrhythmias, the amplitude, duration, wave form, and wave propagation characteristics of the EGG have been infrequently studied.

EGG, because of its noninvasive nature, will continue to aid basic researchers in their quest for additional information about gastric myoelectric activity, gastric motility, and their relationship in normal and pathophysiological conditions. Applied research using the EGG by gastroenterologists is increasing rapidly, largely due to the ease and reliability of its use in detecting gastric dysrhythmias and the recently established relationship between gastric dysrhythmias and upper GI disorders, including delayed gastric emptying and nausea. A related exciting new area that requires EGG recording in order to assess results is electrical pacing of the stomach. Research is currently being carried out on dogs and on a small number of humans in cases of gastric paresis where the stomach has ceased contracting and no drugs are helpful. A less dramatic but related area of research that is currently underway is biofeedback of EGG for individuals with gastric dysrhythmias in an effort to restore normal 3 cpm activity and thereby relieve nausea. The recent increase in the use of the EGG by gastroenterologists has brought with it refinements in both hardware and software, including ambulatory units that have flown on Space Shuttle flights. It is predicted that with the availability of this new equipment, additional psychophysiologists will soon be using the EGG to study the effects of stress and emotions on gastric activity.

DISCRIMINATION

Discrimination is negative behavior directed at individuals or at groups of individuals because of their social group

membership. Discrimination is based on social categories that individuals do not generally choose to belong to, including gender, race, religion, disability, sexual orientation, stigma, age, and physical appearance. Although it is normal to favor people who are similar to us (young children frequently play within gender groups and people date and marry primarily within their own race), discrimination involves unfair, unwarranted, and unjustifiable treatment of others.

Discrimination occurs in both *explicit* and *subtle* forms. Explicit discrimination ranges from actions such as making negative comments to or about people or excluding them from activities, to verbal and sexual abuse or physical harm. Subtle discrimination includes actions that are normally more difficult to detect, such as failing to make eye contact with someone, staring at or avoiding someone, or ignoring them entirely. Explicit discrimination is usually assessed through survey methodology in organizations or through examination of historical records. Subtle discrimination is frequently assessed in laboratory contexts using unobtrusive measures of verbal and nonverbal behavior, such as how much help research participants give to another person, how long they converse with them, or how far away from them they sit.

Discrimination is multiply determined at psychological and sociological levels. At the level of the individual, some people are more likely to discriminate than others. Discrimination is closely related to holding negative stereotypes about members of other groups and to being prejudiced toward them, and it occurs when people choose to act on their negative stereotypes and prejudices. Discrimination also occurs in part because it helps maintain individuals' personal esteem and social identity. People may feel better about themselves and their own groups when they put down, insult, or degrade members of another group. People may also assume that individuals from other groups hold different beliefs and values and therefore dislike them.

At a social level, discrimination is in large part the result of social conformity. If people perceive that the relevant social norms favor discrimination, then they will discriminate themselves; if they perceive that the norms do not allow discrimination, they will not discriminate. Interventions designed to alleviate discrimination frequently attempt to change social norms, with the expectation that this will reduce discrimination. At a societal level, discrimination occurs more frequently when economic conditions are poor. As one example, lynching of Blacks in the South during the early twentieth century was inversely correlated with the price of cotton (an indicator of economic prosperity). This relationship is in part due to the frustration caused by hardship and in part due to realistic conflict caused by employment scarcity. Discrimination may be socially sanctioned because high-status, powerful, individuals are motivated to retain their status by discriminating against lower-status groups.

It is frequently difficult to identify discrimination (even if it is explicit) because most instances leave room for interpretation. In a case where a more qualified female is passed over for a position and a male is hired instead, one can only be certain that discrimination has occurred when gender is the sole difference between the two candidates or if there is a continuing pattern of unequal treatment by the employer over time. In many cases, there is not enough information to allow an unambiguous attribution. Thus, even though discrimination may have occurred, it may not be easily interpreted as such, and therefore may not be perceived or reported.

Although members of targeted groups (for instance, women and African Americans) report that there is discrimination directed at their group as a whole, they do not generally report experiencing it personally. People may deny personal discrimination because admitting that they are victims is psychologically costly. There are also many social costs to reporting discrimination (such as embarrassment, ostracism, and employment harassment) that make people unlikely to do so.

Discrimination can be both psychologically and physically harmful to those who endure it. Individuals who report frequent exposure to discrimination or unfair treatment also report experiencing more psychological distress, depression, and lower levels of life satisfaction. Discrimination may contribute to the high percentage of minority group members who live in poverty and lack access to high-paying jobs. Discrimination also is responsible in part for higher mortality rates, access to less and poorer quality healthcare, delayed diagnoses, or failure to manage chronic diseases for members of minority groups.

If the targets are aware of the discrimination they are experiencing, they may place the blame internally, and this may result in lowered self-esteem, self-blame, and disidentification with the ingroup. On the other hand, they may also place the blame externally, which can lead to either individual action (such as leaving the negative situation or reporting or confronting perpetrators) or collective action (such as mobilizing political or other organizations).

Political policies in the United States, including the Civil Rights Act of 1964, which established the Equal Employment Opportunities Commission and prohibited discrimination in employment, have reduced the frequency of explicit discrimination in recent years. The courts have ruled that even unintentional discrimination violates equal status laws. If targets are harmed, degraded, or treated differently than others as a function of their group membership, then discrimination has occurred. These laws have also required reparations for violations of the laws, including awarding employment, promotions and back salary, and have in some cases requested employers to establish practices that require a certain number or percentage of members of victimized social groups to be hired or promoted. Despite a reduction in explicit discrimination, im-

plicit forms of discrimination continue to be common. Current research shows that women and minorities generally report experiencing discrimination on a weekly basis.

DISPLACEMENT

Displacement of aggression refers to a redirection of harm-doing behavior from a primary to a secondary target or victim. An early theory of displacement was proposed by Sigmund Freud in *Beyond the Pleasure Principle* (1950). Freud suggested that persons tend to attack the sources of frustration, but if an individual cannot attack such a source because the target is unavailable or too powerful, a substitute target may become the victim of the pent-up anger. This mechanism explained apparently irrational behavior, such as a person's killing a total stranger for no apparent reason. Frustration causes a buildup of inner tension, which is expended when the individual expresses aggression toward a target. The amount of aggression is postulated to be directly related to the amount of cumulated inner energy. A sudden release of energy through aggressive action is referred to as catharsis.

In *Frustration and Aggression* (1939), Dollard, Doob, Miller, Mowrer, and Sears converted the literary and metaphoric language of Freud into the scientifically more acceptable, positivistic language of laboratory-oriented behavioristic psychologists. According to Dollard and his colleagues, aggressive behavior—like all other kinds of behavior—should be considered subject to the laws of learning. They defined *frustration* as any stimulus that blocked the goal attainment of an organism striving to attain a goal. Frustration causes a buildup of aggressive drive, which presses for behavioral expression in the form of harm-doing. When a person directs an aggressive response at a frustrating agent and the response is successful in removing the barrier to goal attainment, aggression is rewarded. A rewarded response is more likely to recur the next time the individual faces a similar situation. Thus, while harm-doing behavior reduces aggressive drive and additional immediate aggression, it is rewarding and increases the likelihood of harm-doing when the individual is frustrated again in the future.

Rewarding an individual for inhibiting an aggressive response or punishing harm-doing behavior may teach self-control. As a result of learned inhibition, the aggressive energy generated by frustration either continues to build up or is expressed in indirect ways. While fear of punishment inhibits aggressive behavior, the cumulated internal energy pushes for its expression. These two conflicting forces were conceptualized by Miller (1948) in terms of a model incorporating approach and avoidance forces, but this conflict model has had little subsequent impact on research. Displacement is essentially a principle of substitution of responses or of targets and may be viewed in terms of response or stimulus generalization.

The concept of displacement has been used to explain a wide variety of behaviors; for example, ethnic prejudice and discrimination may be considered a form of displacement. Thus, researchers have tried to show that historically a decline in cotton prices in the southern United States was associated with an increase in lynchings of African Americans. The reasoning is that bad economic results were frustrating to farmers, who took out their anger on Blacks—a type of scapegoating theory. Similarly, wars have been considered to be a result of the cumulated frustrations of many people manifested in an aggression toward a substitute target: the enemy nation. The importance of understanding displacement effects is certainly underlined by the frequent reference of the concept to ethnic, racial, and religious conflicts; child abuse, lynchings, riots, suicides, revolutions, and many other important social behaviors.

The establishment of the frustration-aggression interpretation is undermined by evidence failing to demonstrate catharsis effects (the reduction of subsequent aggression immediately following aggressive behavior). Furthermore, there is no evidence of a buildup of more intense aggressive behavior over a series of frustrating experiences. The fact of displacement-like effects is indisputable, and alternative theories are being developed that rely on concepts drawn from factors related to interpersonal interactions rather than intrapsychic dynamics. Among these alternative explanations are active downward comparisons, self-presentation, negative equity, and guilt by association. Active downward comparison refers to an individual's efforts to lower the performance or identity of another person or group so as to enhance his or her own identity (Wills, 1981). For example, acting to block the opportunities of others (such as providing them with inferior schools) serves to maintain the relative superiority of the discriminating person or group. The desire for positive self-esteem is considered the motivating factor.

Tedeschi and Norman (1985), however, argued that putting others down raises the self up, not so much for internal self-esteem reasons but for the purpose of presenting oneself to others as better or superior in some way. In this formulation, individuals are highly motivated to establish and maintain desirable identities in order to foster positive and rewarding interactions with other people. As a result, an individual is willing to harm someone else if doing so will help promote a positive identity for the individual in the eyes of others. The victims of such harm-doing may

have done nothing to provoke or justify the action. For example, a group of teenage boys, each one of them motivated by the desire to impress the other boys with his willingness to use violence, may attack someone at random.

Motivation to restore equity may also produce displacement-like behavior. Members of most groups expect rewards to be fairly distributed. The rule of equity prescribes that each member should receive a share of the rewards proportional to his or her contribution to the group's success in attaining the rewards. It is assumed that people are motivated to maintain justice and that, when an injustice occurs, something should be done to restore justice. When rewards are unfairly distributed in a group, disadvantaged members may be motivated to restore equity. If for some reason no action can be taken against the source of the inequity, other means of restoring equity may be undertaken. For example, if a boss distributes Christmas bonuses to his or her workers, and a few of the workers believe they received unfairly low bonuses, they should be motivated to restore equity. They cannot punish the boss for fear of losing their jobs, but they might take out their anger by harming (probably in some nonviolent way) the relatively advantaged workers. Such action restores equity in the sense that the advantaged workers are made to suffer, detracting from the monetary gain and thus making outcomes more fair.

Anthropologists and historians have noted that retaliation is often visited upon coconspirators, blood relatives, or friends of instigators, rather than directly against the instigator. Victims sometimes hold all members of an outgroup equally responsible for harm done to them and may retaliate against one of the weaker members of the outgroup. Thus, retaliation may be directed against any member of a rival gang, or in blood feuds, against any member of the target family. Hate groups may randomly target any member of the hated group. The representative target chosen from the category of believed enemies may be completely innocent and unaware of any harm done to the aggressor. The attack represents a displacementlike effect, since revenge is not taken against a frustrating agent but against an innocent third party—although such an attack may serve to punish the frustrating agent by harming a loved one, or it may be motivated to deter future harmdoing by that agent.

DOCTOR OF PSYCHOLOGY DEGREE (PsyD)

The Doctor of Psychology degree (PsyD) is awarded to psychologists whose education and training are designed to prepare them for careers in professional practice. With considerable variation in content and emphasis, the training programs that lead to the degree all include education in basic facts and principles of psychology, extensive supervised experience in application of procedures for the assessment and modification of psychological functioning, and an internship. Early proposals for PsyD programs did not include a doctoral dissertation requirement, but nearly all the programs now in operation do so. Systematic inquiry is regarded as a form of practice rather than an end in itself, and the range of topics is broader than has traditionally characterized PhD dissertations in psychology. Community needs analyses, case studies, and theoretical inquiries, among other kinds of investigations, are all acceptable, so long as each project contributes to improved understanding or constructive change in the way psychologists do their work. A typical program requires 5 years of graduate study beyond the baccalaureate degree.

The first proposal for use of the PsyD was advanced by Leta Hollingworth in 1918. Similar proposals were put forward by Loyal Crane in 1925 and A. T. Poffenberger in 1938. All argued that education in the science of psychology was insufficient for the practice of psychology and that the PhD degree, traditionally used as a scholarly credential across all disciplines, was inappropriate as a certificate of knowledge and competence in professional psychology. They urged development of programs expressly designed to prepare people for practice, and awarding a professional doctorate analogous to the MD, DDS, and other professional degrees upon completion of graduate studies. The proposals were not cordially received in the academic community, however, and only two practitioner programs, both in Canada and both short-lived, were attempted before the 1960s.

A conference on training in clinical psychology at Boulder, Colorado in 1949 established the scientist-practitioner model as the dominant pattern for the education of professional psychologists and the PhD as the standard qualify-

ing credential. In the Boulder model, as it came to be called, students were to be prepared as researchers as well as clinicians, in the belief that each form of activity would enhance the other. The Boulder model was widely adopted in American universities and remains the most common design for the education of professional psychologists.

By the middle of the 1960s, however, expressions of discontent with prevailing PhD programs were often heard. According to critics, most clinical programs in academic departments overemphasized research at the expense of training for practice, and psychologists entering professional careers, as more than half of them were doing by that time, were poorly prepared for the challenges they faced in their work. After lengthy deliberations, an American Psychological Association (APA) committee on the scientific and professional aims of psychology recommended the establishment of practitioner programs leading to the PsyD degree. The proposal was debated at a conference on training in clinical psychology in Chicago in 1965, where it was not generally endorsed, although the majority recognized that programs of this kind might be attempted in some universities and that the results of those efforts would provide a basis for evaluation at a later time. Shortly after the Chicago conference, the faculty of the Urbana-Champaign campus of the University of Illinois voted to inaugurate a PsyD program, and the first program in the United States was established there in 1968.

Five years later, still another conference on training in professional psychology was held in Vail, Colorado. There the concept of direct education for the practice of psychology was endorsed, as was the use of the PsyD degree to certify completion of graduate work in practitioner programs. In the years that followed, additional PsyD programs were developed in universities and professional schools throughout the United States, although the initial program at the University of Illinois was discontinued in 1980.

Beginning in the 1980s and continuing into the 1990s, long-standing educational policies that restricted use of the PhD to mark the highest level of achievement in preparation for careers of creative research and scholarship, and to mandate the use of professional doctoral degrees to recognize completion of academic preparation for professional practice, were actively enforced by agencies responsible for accrediting educational institutions in the United States. During this period, a considerable number of practitioner programs that had previously awarded the PhD were required to employ the PsyD degree to maintain approval. This change, along with continuing development of new programs, led to substantial expansion in the number of PsyD programs in the United States and Canada. Toward the end of the twentieth century, some 60 programs were in operation. Approximately half of these were in universities, half were in free-standing professional schools, and two-thirds had been fully or provisionally approved by the APA Committee on Accreditation.

DOPAMINE SYSTEMS

Perhaps more than any other neurotransmitter, dopamine has received attention for its potential involvement in psychiatric disorders ranging from Substance Abuse to Schizophrenia. This focus relies primarily on the capacity of drugs that manipulate dopamine transmission to ameliorate or exacerbate psychiatric conditions. However, our emerging comprehension of brain circuitry and function permits an understanding of dopamine transmission in the brain that is both more integrated and accurate. This short description of dopamine systems will explicate the components of dopamine transmission, such as synthesis, release, and receptor signaling, and using brain circuitry to assemble the dopamine neurons and projections into overall brain functions.

Dopamine: The Neurotransmitter

Anatomical Organization

Akin to other monoaminergic transmitter systems, the dopamine neurons are located in discrete brain nuclei and are not widely distributed throughout the brain. The largest cluster of dopamine cells is located in the ventral midbrain. The medial portion of cells is located in the ventral tegmental area, while the lateral cluster is in the substantia nigra. In addition, another large group of cells is located in the hypothalamus. This latter group functions primarily to regulate prolactin secretion from the pituitary, while the midbrain neurons project to areas of the forebrain and cortex involved in motor, emotional, and cognitive processing. This includes projections to aspects of the extrapyramidal motor system, prefrontal cortex, and various limbic structures such as the amygdala and hippocampus. These projections are topographically organized, with the more medial neurons providing innervation to the cortex and limbic nuclei, and the more lateral cell group providing innervation primarily to the caudate. Moreover, within certain axon terminal fields there is a medial to lateral topography. For example, in the ventral pallidum or subthalamus, the ventral tegmental area innervates the medial aspect of the nucleus, whereas the substantia nigra innervates the lateral compartment.

Synthesis, Degradation, and Release

Dopamine synthesis is a multiple enzymatic process involving the hydroxylation and decarboxylation of tyrosine. The rate-limiting enzyme in the synthesis of dopamine is tyrosine hydroxylase, which catabolizes tyrosine into dopa. This is a highly regulated enzyme susceptible to end-product feedback by cytosolic dopamine as well as by released dopamine via stimulation of dopamine autoreceptors. Following synthesis, dopamine is transported from the cytosol into synaptic vesicles via a proton-dependent vesicular monoamine transporter and is then sequestered pending release into the synaptic cleft. The physiological release of dopamine is voltage- and calcium-dependent and is regulated by the frequency and pattern of action potentials as well as by dopamine autoreceptors. A burst pattern of action potentials is most efficient at releasing dopamine. Dopamine in the synaptic cleft is eliminated by one of three mechanisms: (1) The vast majority of dopamine undergoes reuptake into the presynaptic terminal via the dopamine transporter; (2) A minor metabolic inactivation in the synaptic cleft involves methylation via catecho-O-methyltransferase to form 3-methoxytyramine; or (3) Dopamine can diffuse into the perisynaptic extracellular space. Following transport into the presynaptic terminal, dopamine is either transported into synaptic vesicles or oxidized by monoamine oxidase. Monoamine oxidase is primarily located in the mitochondria and exists as two isozymes (MAO-A and MAO-B). The two isozymes are differentially distributed in the brain and have different affinities for monoamines. Monoamine oxidase-B is of greater importance in metabolizing dopamine in the nigrostriatal pathway, whereas MAO-A may be of greater importance elsewhere.

Dopamine Receptors

Receptor Subtypes

Dopamine receptors can be localized on neurons postsynaptic to dopamine terminals (postsynaptic receptors), on dopamine axon terminals (autoreceptors), on nondopaminergic axon terminals (heteroreceptors), or on dopamine cell bodies and dendrites (somatodendritic autoreceptors). Dopamine receptors are synthesized from five different genes and, based upon sequence homology and pharmacological specificity, have been divided into two receptor families. The D1 receptor family consists of the D1 and D5 receptors while the D2 family consists of D2, D3, and D4 receptors. Two splice variants of the D2 receptor subtype have been characterized: D2S and D2L.

Receptor Localization

The various dopamine receptor subtypes are heterogeneously distributed in the nervous system. The D2 receptors are found both postsynaptically and as presynaptic autoreceptors, while the D1 receptors are located postsynaptically and heterosynaptically on nondopaminergic axon terminals. Thus D2 receptors, notably the D2 and perhaps D3 subtypes, regulate the release and synthesis of dopamine in response to stimulation by extracellular dopamine. Remarkably, in certain areas where dopamine receptors are in highest density, such as the striatum and substantia nigra, the cells expressing each receptor subtype are distinct. Within each family there also exist distinct distributions of receptors. For example, in the D1 family the D1 subtype is highest in the striatum, olfactory tubercle, amygdala, and parts of the cortex, whereas the D5 subtype is most dense in the thalamus and hippocampus. Similarly, for the D2 family, D2 receptors are dense throughout the basal ganglia, whereas D3 receptors are localized to the more limbic, ventral portions to the striatum and olfactory tubercle, and D4 receptors are found primarily in the prefrontal cortex and hippocampus.

Receptor Signaling

All of the dopamine receptor subtypes are metabotropic, G-protein coupled receptors. The two families of receptors have distinct intracellular signaling mechanisms. The D1 family couples with Gs to activate adenylate cyclase and cAMP production. The ensuing activation of protein kinase A results in the phosphorylation of numerous proteins leading to changes in enzyme activity, signaling in other receptor systems and gene expression. Notably, there is a heterosynaptic inhibition or stimulation of the release of other neurotransmitters, as well as a stimulatory effect on voltage-dependent calcium channels. The transduction pathway for the D2 family of receptors is more complicated, but involves coupling to Gi and Go. The two most well-studied signaling pathways are the inhibition of adenylate cyclase and the opening of potassium channels. These actions result in numerous changes in cell functioning. Notably there is a hyperpolarization of membrane potential, due primarily to the opening of potassium channels, which accounts for the inhibition dopamine release by D2 autoreceptors and the inhibition of postsynaptic neurons.

Receptor Pharmacology

The pharmacological stimulation of dopamine receptors can be produced by two types of agonist. Direct agonists have affinity for the dopamine receptors themselves, whereas the indirect agonists stimulate dopamine receptors by increasing the concentrations of dopamine in the synaptic cleft. Both types of agonist have clinical utility. The indirect agonists produce increases in extracellular dopamine by binding to the dopamine transporter and either preventing dopamine transport or acting as a false substrate. Amphetamine typifies a false substrate that is

transported in place of dopamine. Additionally, the false substrates promote the heteroexchange of dopamine, causing reverse transport through the transporter. Therefore, drugs like amphetamine not only prevent the elimination of dopamine from the synaptic cleft but also induce release of cytosolic dopamine via reversal of the transporter. Cocaine and methylphenidate are prototypic drugs that bind to the transporter to prevent the reuptake of dopamine but are not themselves transported. Therefore, the increased release of dopamine by these latter drugs relies solely on the accumulation of dopamine released from synaptic vesicles and does not result from heteroexchange. Direct agonists bind to dopamine receptors and may or may not be selective for the D1 or D2 family of receptors. Given the heterogeneity of receptor localization (discussed previously), the development of highly selective compounds would seem to provide for relatively subtle manipulations of dopamine transmission. While drugs exist to clearly distinguish the D1 and D2 families, no drugs are universally accepted to distinguish between the receptor subtypes within each family. However, progress has been made recently in developing drugs to distinguish the D2 from the D3 receptor. Similarly, dopamine receptor family selective antagonists are well characterized, but the development of antagonists selective for the receptor subtypes within each family is not well evolved. Nonetheless, as outlined in the next section, certain drugs are somewhat preferential for one receptor subtype versus another and the relative clinical utility of these drugs has led to considerable speculation regarding involvement of one versus the other subtype in psychiatric disease processes.

Physiology of Dopamine Systems

Dopamine neuronal activity is regulated by a variety of neurotransmitters in the ventral midbrain. The neurons themselves are what one might call *leaky* and will initiate spontaneous action potentials in addition to being driven by various inputs. In general, the activity of dopamine neurons responds to changes in an organism's environment. A novel stimulus activates dopamine cells regardless of whether the stimulus is of positive (e.g., reward) or negative (e.g., stress) valence to the organism. Thus, activation of dopaminergic pathways serves to cue the animal that an important environmental event has occurred in preparation for engaging in an adaptive behavior. Given this function it is rational that the most dense dopaminergic innervation is to the limbic and motor regions of the forebrain. For example, when an animal undergoes a stress or is exposed to a cue, such as the possibility of sex or food, that signals a positive reward, there is an increase in dopamine release in the nucleus accumbens (a portion of the ventral striatum thought to be a particularly critical interface for integrating emotions with adaptive motor responses).

Pathophysiology of Dopamine Systems

Parkinson's Disease

Parkinson's disease is characterized as a degenerative movement disorder that very clearly results from a loss of dopamine neurons in the substantia nigra and an ensuing loss of dopamine innervation to the basal ganglia. The motor disorder progresses from tremor and slurred speech to akinesia and rigidity. The treatment of Parkinson's disease is initially dopamine replacement in the form of the dopamine precursor l-dopa. However, to be effective, sufficient dopamine synthetic capacity must be available in axon terminals in the basal ganglia. Thus, as the degeneration progresses, l-dopa becomes a progressively less effective treatment. Based upon understanding of basal ganglia circuitry, manipulating other neurotransmitters such as acetylcholine is also useful in ameliorating the motor symptoms of Parkinson's disease. However, no treatment is available that reverses or inhibits the neurodegeneration.

Substance Abuse

The dopamine projection from the midbrain to the nucleus accumbens is thought to be critical in the development of addiction to most drugs of abuse. Indeed, many drugs such as cocaine, amphetamine, ecstasy, and nicotine have been shown to directly activate dopamine neurons or release dopamine. Even drugs such as alcohol or heroin that do not directly bind to dopamine neurons are thought to produce addiction, at least in part, via indirect stimulation of mesoaccumbens dopamine release. The release of dopamine by these drugs elevates dopamine substantially higher than the level that occurs following physiological response to a stress or a natural reward (mentioned earlier). Such aphysiological elevations precipitate changes in gene expression in dopamine cells and elsewhere in limbic and motor circuits and ultimately mediate the behavioral changes associated with addiction. Given the apparent role of dopamine in addiction it would be predicted that dopamine antagonists might be useful in treating addiction. However, this has not proven to be the case, presumably because the repeated use of drugs in addiction produces neuroplastic changes beyond dopamine transmission that can mediate the cravings and sensitivity to stress that cause relapse to drug taking.

Schizophrenia

The dopamine hypothesis of Schizophrenia remains a well considered postulate of both the etiology and symptomatology of Schizophrenia. The primary buttresses of this hypothesis are that certain symptoms of Schizophrenia are ameliorated by D2 family dopamine blockers, and that dopamine agonists exacerbate these symptoms. Moreover, there is some evidence to indicate that prophylactic ad-

ministration of dopamine antagonists inhibits the progressive amplification of psychosis that sometimes occurs in Schizophrenia. Although dopamine is no doubt involved in Schizophrenia it appears that defects in different pathways mediate different symptoms and that the primary defect may be in transmitters that regulate the dopamine systems. For example, a deficit in dopamine transmission in the prefrontal cortex may mediate certain cognitive symptoms, whereas enhanced dopamine transmission in the nucleus accumbens likely plays an important role in mediating the positive symptoms of psychosis, such as paranoia. Indeed, a number of current hypotheses regarding the etiology of Schizophrenia rely on the primary defect residing in limbic excitatory input to the prefrontal cortex.

Conclusions

Dopamine is a monoamine transmitter that has been linked to a surprising number of neuropsychiatric disorders. It is among the most well-characterized transmitter systems, and drugs manipulating dopamine release and receptor occupation profoundly modify behavior in both a therapeutic and maladaptive manner. Physiologically, dopamine appears to function in linking emotional state with adaptive behavioral responses. Thus, dopamine is perfectly situated to be at least indirectly involved in many psychiatric disorders that are manifested as a maladaptive mismatch between environmental stimulus and behavioral response.

DOUBLE BIND

Double bind is a concept characterizing an ongoing pattern of communication that imposes painful no-win situations upon its victim through two processes: first, through contradictory demands made at different levels of communication, and second, by preventing the victim from either discriminating and commenting on the bind or withdrawing from it. Originally studied in the relationships between schizophrenic adults and their families, the double bind was viewed as having had causal relevance for their Schizophrenia through having impaired their capacities to derive clear meaning from communications and to participate in normal social relationships.

The original clinical studies leading to the double bind concept were conducted in Palo Alto, California, in the 1950s and 1960s by Gregory Bateson, Don D. Jackson, Jay Haley, and John H. Weakland (1956), a group of clinicians and scholars who collectively introduced a communication theory approach to the mental health field through pioneering contributions to the development of family therapy. Their work emphasized that there are, within families as within the individual's internal environment, homeostatic or stability-making processes that regulate their functioning and contribute to their survival. Within families, communication serves this function.

A single, complex human communication can contain many messages of different logical types, often involving separate modalities that can contradict or reinforce one another. An aggressive utterance might, for example, be qualified by movements, postures, or voice tones conveying that "this is all in fun." Even the relationship of the message to surrounding events or shared past experience may contribute to its meaning. Put entirely into words, this multilevel message might mean that "I pretend to show aggression in jest because our relationship is such that, under the circumstances, you will find it funny and feel warmly toward me."

In its regulatory role in human interaction, communication carries substantial responsibility for defining the nature and limits of the relationships between or among people and, therefore, the roles appropriately played by each person in a given interaction. The communicational approach holds that each transaction between the parties to a communication involves a relationship message proffering or affirming a relationship of a particular sort and a response that accepts, modifies, or negates the definition communicated. Thus by the act of scolding, a parent affirms the right to scold in the relationship with that child. The angry transactions between adolescents and their parents may well have less to do with the apparent content of the quarrel than with the relationship changes being forged and contested.

Considerable learning, often nonverbal, is involved in the capacity to decode communications, particularly those involving apparent contradictions between levels, as with angry words said laughingly. When meaning is not apparent, people learn to shift to a more abstract level and to communicate about communication, thereby clarifying the meaning of ambiguous messages. Children initially lack

this capacity; if they are blocked from learning how to learn about meaning, serious adulthood disorders may result. The double bind involves a communication style which is pernicious in its reliance upon internal contradictions and blocked learning. As studied in the families of schizophrenics, it appeared often in mother-child relationships in which the mothers seemed not to want to be understood: They could accept neither their children nor their rejection of those children. The double bind describes their covert pursuit of distant relationships disguised by reciprocal shows of loving behavior. Such parents appeared to invite closeness at one level while negating it at another. A child who responded by approaching was covertly rebuffed, yet efforts to withdraw were also punished. In addition, efforts to shift levels and to question the meaning of the interactions were punished, impairing the child's capacity to form and trust impressions of reality.

While the double bind as an ongoing pattern cannot be fully represented in a single transaction, the following vignette illustrates many of its features. A young woman hospitalized for Schizophrenia improved enough to select and purchase clothing for her first hospital leave. When her parents came for her, however, her mother showed immediate distress over her juvenile taste in clothing and agitatedly undressed her and regarbed her in items of the mother's own choosing. "There," the mother said, "now you look all grown up!" The leave went badly and the daughter was soon back in an acutely psychotic condition.

The mother's emphatic behavioral rejection of her daughter's independence was belied by the verbal message that she urgently must look grown up, indicating to hospital staff a probable conflict regarding the relationship: The patient must be an adult and therefore independent, yet a child and therefore dependent. In responding to movement toward independence, the injunction never to be independent was more emphatic than that to be always independent. Enjoined to be a woman and a child, independent and dependent, close and far, the patient responded with disturbed, psychotic behavior. A woman made childlike by an illness, she was incapable of independence, yet too disturbed to be at home: She was neither too close nor too far. Her relationship to her mother was preserved.

In the decades since the concept of the double bind was introduced, it has found widespread use in and beyond our culture as a means to describe patterns of covertly contradictory communications and their pernicious effects on the targeted person. The difficulties of studying these sorts of complex family communications, the complexities of Schizophrenia research, and a pendulum swing toward biological explanations hindered double bind research. Interest has apparently faded regarding the original concept that a predisposition to Schizophrenia can be created by prolonged participation in double binds within the family. Even so, research on this topic continues here and abroad, with periodic demonstrations of its relevance to understanding Schizophrenia.

DREAMS

The study of dreams has changed its focus from meaning to the underlying neuroscience mechanisms that are involved in their generation. Current research suggest that cortical areas involved in dreaming reflect those areas associated with emotional and sensory processing and lack involvement of higher-level logical thinking.

Historical Introduction

Since the beginning of recorded history dreams have played a role in humans' attempt to make meaning of the world and ourselves. Dreams have represented the other, the aspects of ourselves and our world that stood outside of human knowledge or could not be understood within the current paradigm. As illustrated in a variety of religious texts over the last few thousand years, dreams have foretold future events as well as allowed for communication with the gods. Still, during this period others, including the Roman poet Lucretius in 44 B.C., suggested that dreams are common in all animals. Darwin echoed a similar theme in his *The Descent of Man* (1871), in which he suggests that all higher animals, including birds, have dreams. Within the last 100 years the understanding of dreams has been brought into a more theoretical perspective within dynamic and analytic psychology and more recently within the context of the neurosciences. Although a topic of heated debate, an initial contribution was Freud's perspective that dreams could be understood within the context of instinctual functioning and the neurology outlined in the *Project for a Scientific Psychology.* As articulated in the *Project,* dreams offered an understanding of previously established networks of neurons and pointed to the manner in which ideas and events had come to be associated with one another in the brain. In this way dreams were reflective of an individual's psychology during the waking state. Jung had a more evolutionary perspective in which he viewed specific processes in our environment as triggers for bringing forth action patterns, or *archetypes* as he called them, much in the same manner as described by the ethologists. Dreams in this context reflect these evoked archetypical patterns.

Beginnings of Empirical Research

Many view the scientific study of dreams beginning in 1953 with the discovery by Aserinsky and Kleitman of an association between dreaming and rapid eye movement (REM) sleep. Sleep generally is characterized by four different stages as reflected in the electroencephalogram (EEG). In contrast to the higher-voltage more-patterned EEG activity found in sleep, REM sleep appears to have an EEG pattern more like that of the waking state, also is referred to as *paradoxical sleep,* and is characterized by low-voltage random-appearing EEG activity. Awaking an individual during REM sleep is more likely to result in a dream report than any other sleep stage. Following the discovery of the association between REM sleep and dreams, a variety of labs examined the dream state. The work included a variety of foci including the nature of the dream itself, factors involved in dream recall, the influence of external factors on dreaming, and other factors associated with dreaming. For example, following a natural disaster such as an earthquake, researchers have found an increase in nightmares, suggesting that trauma can be related to dreaming. Another type of research has shown increased REM sleep when learning a new task in both humans and animals, which suggests that activity during REM sleep may be associated with consolidating new information into long-term memory. Dream research has used a variety of theoretical perspectives including a more cognitive one. The main characteristics of dream process include emotionally laden sensory processes and images without a sense of individual control. Less well understood is the so-called *lucid dream,* in which an individual realizes while dreaming that he or she is part of a dream and may even experience control of the dream. Lucid dreams are rare and occur in only 1–2% of all reported dreams.

Neuroscience Studies

More recently, dream processes have been examined within the context of current neuroscience work with the goal of determining brain areas involved in dreaming and the manner in which dreaming and other cognitive processes (e.g., visual imagery) are related. Early speculation suggested that dreams were related to brain-stem functioning especially the pons with its generators for REM sleep. However, neuropsychological case studies have shown that damage to the pons does not stop dream reports, whereas damage to the forebrain areas does. Current brain-imaging studies suggest that a variety of brain areas are active during brain states associated with dreaming. These areas include the brain stem, which is responsible for basic arousal; the limbic system, which is highly involved in emotionality; and forebrain areas involved in sensory processing. Areas involved in higher-level cognitive processes such as planning and logical thinking showed decreased activation during these dream periods. Further explorations suggest that pathways between areas involved in emotional processing and those involved in visual processing are active, whereas those between visual processing and higher-level logical thinking are not. This may help to explain the nature of dreams in which emotional and nonlogical sequencing of imagery are accepted without reflective awareness. One implication that can be drawn from the brain-imaging work is that a variety of processes are involved in the creation of dreams and that such work helps to characterize the nature of the subjective experience of dreaming.

DRUG REHABILITATION

In 2000, the National Household Survey on Drug Abuse estimated that approximately 14 million Americans, or 6.3% of the population, used an illicit drug during the previous month (Office of Applied Studies, Substance Abuse and Mental Health Services Administration, 2001). Of those 14 million people, approximately 4.3 million met the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV;* American Psychiatric Association, 1994) diagnostic criteria for Substance Abuse or Dependence. Thus, the treatment and rehabilitation of drug abusers remains a pressing public-health need and a challenge for mental health professionals.

To some, drug rehabilitation refers primarily to the treatment of intravenous heroin users or daily users of cocaine. However, treatment and prevention efforts targeting lower levels of drug use have also become widely available. The *DSM-IV* recognizes 11 categories of Substance Use Disorders: alcohol; amphetamines; caffeine; cannabis; cocaine; hallucinogens; inhalants; nicotine; opioids; phencyclidine (PCP); and sedatives, hypnotics, or anxiolytics. Moreover, patients can be diagnosed with Substance Abuse (recurrent and significant adverse consequences related to use) or, in more serious cases, Substance Dependence (continues use despite negative consequences, tolerance, withdrawal, and compulsive use). Thus, a random selection of patients in drug rehabilitation might include a heroin addict, a chronic

marijuana user, a person who abuses prescription pain medications, or an adolescent who uses ecstasy every weekend. The expanded range of individuals seeking or being referred to drug rehabilitation has necessitated the development and evaluation of an increasingly diverse group of treatment strategies.

In most cases, the ultimate goal of treatment is helping the patient achieve lasting abstinence. More immediate goals often include reducing drug use; improving interpersonal, occupational, and community functioning; and reducing the negative medical and social consequences of drug use.

Pharmacotherapy, or the use of medications, can be an important element of treatment for certain types of Substance Dependence. One of the best examples of pharmacotherapy is the use of methadone in the treatment of heroin dependence. Methadone is an opiate agonist, meaning that it is chemically similar to heroin and produces some of the same effects. The use of methadone in the treatment of opiate dependence has several advantages, including the prevention of opiate withdrawal, reduction or elimination of the euphoric effects of heroin, reduced use of illicit drugs, and stabilization of other life domains. However, it is generally recognized that pharmacotherapy work best when used within the context of a more comprehensive treatment plan.

Group and individual counseling, and other behaviorally based treatments, are also critical components of drug rehabilitation. Group therapy attempts to foster a supportive atmosphere in which patients can learn from one another as they try to make positive life changes. Groups can consist entirely of current or former drug abusers, such as those employed by Alcoholics Anonymous, Narcotics Anonymous, and other self-help organizations. Groups that are directed by a mental health professional and follow a more structured format are also widely available.

Individual counseling tends to combine strategies directly aimed at reducing drug use with the discussion of other life domains. Increasing motivation, understanding the antecedents and consequences of drug use, severing ties with other drug users, and the development of drug-refusal skills are some of the commonly used techniques that counselors use to help patients reduce their drug use. Other life areas that often need to be addressed over the course of counseling include physical and mental health, interpersonal and family relationships, education and occupational achievement, involvement in the community and other drug-free activities, spirituality, development of effective problem-solving skills, and help with legal and financial difficulties.

In 1999, the National Institute of Drug Abuse (NIDA) distilled the last 25 years of drug rehabilitation research into a set of guiding principles. These principles included the endorsement of a number of scientifically based, empirically validated forms of individual counseling. The following are examples of highly regarded, NIDA approved counseling approaches.

Motivational Enhancement Therapy (*MET*) is a client-centered counseling approach designed to resolve the ambivalence many patients have about entering treatment and stopping drug use. This approach employs a number of specific interviewing techniques to increase internal motivation to change. Motivational Enhancement Therapy can be used to reduce drug use, or, in cases with a history of treatment failure, to prepare patients for more intensive forms of treatment.

The *Community Reinforcement Approach* (*CRA*) is an intensive outpatient therapy for the treatment of cocaine addiction. Through weekly counseling, patients learn to reduce drug use and increase involvement in drug-free recreational activities and social relationships. The CRA approach also makes use of contingency management, a behaviorally based strategy that uses a system of rewards and punishments to reinforce abstinence and make drug use less attractive. Patients submit urine samples over the course of treatment, and they receive vouchers for drug-free samples. Vouchers can then be exchanged for goods and services that help promote a drug-free lifestyle.

Multidimensional Family Therapy (*MDFT*) for adolescents is an outpatient family-based treatment for teenagers. In this approach, adolescent drug use is believed to be influenced by factors related to the individual, the family, the peer group, and the larger community. Treatment includes both individual and family sessions and may occur in the clinic, the patient's home, or in the community (e.g., court, school). Both the adolescent drug user and his or her family members are encouraged to take an active role in achieving drug abstinence.

Relapse Prevention Therapy uses a variety of cognitive-behavioral strategies to facilitate abstinence and reduce the risk of a return to drug use. Relapse Prevention Therapy's approach recognizes that many patients will resume drug use after treatment and that most patients will require multiple treatment episodes before they are able to achieve sustained abstinence. Thus, a central element of this approach is helping patients anticipate and prepare for situations that may trigger a relapse.

Drug rehabilitation can occur in various settings, including hospitals and specialty clinics, or with individual mental health professionals in private practice. Treatment for a Substance Use Disorder can also be incorporated into the treatment of other coexisting psychiatric disorders. Short-term residential programs require patients to live at the treatment facility for anywhere from 3 to 6 weeks. Therapeutic Communities (TC) are a special case of the residential treatment program. In the TC, patients with long histories of drug dependence and criminal behavior reside in a highly structured environment for up to 12 months. Prison-based drug rehabilitation programs have also shown some promise and appear to work best when paired

with community-based programs that continue treatment after the patient leaves prison.

DYNAMIC ASSESSMENT

Dynamic assessment refers to an approach to conducting psychoeducational or speech and language assessments that most characteristically involves interacting with the client during the course of the assessment and using the responsiveness of the client to this interaction as a primary source of information.

While there are a number of models and developing procedures that vary on dimensions of content and degree of standardization (Lidz & Elliott, 2000), dynamic assessments often follow a pretest-intervene-retest format. The assessor first determines what the client is able to do without assistance, then proceeds to offer assistance, and finally evaluates the degree and nature of the client's responsiveness to this assistance.

The roots of dynamic assessment extend back into the early twentieth century, where many writers expressed their dissatisfaction with the available approaches to the measurement of intelligence (Lidz, 1987). More specifically, the fatherhood of dynamic assessment is generally assigned to both Vygotsky (1978) and Feuerstein (Feuerstein, Rand, & Hoffman, 1979). Vygotsky's notions of the "zone of actual development" and the "zone of proximal development" are definitive of these procedures. Feuerstein's descriptions of "mediated learning experiences" have influenced the development of the interventions offered during the assistance phases of the procedures. It was also Feuerstein who operationalized the notion of dynamic assessment in his Learning Potential Assessment Device.

Research and development regarding these procedures had been essentially parallel in the United States, Europe, and Israel. However, more recently, with European publications increasingly available in English, these developments have cross-seminated and current publications tend to present articles and chapters from multiple and diverse sources.

There are essentially four primary models of dynamic assessment. The first, which is characteristic of Feuerstein and colleagues' approach, is the most loosely structured and diagnostically oriented. The intervention provided to the examinee is tailored to the responses and responsiveness of the examinee, with little preprescription. The second, which characterizes the approach designed by Budoff (1987), offers a standardized intervention to all examinees, based on predetermined strategies relevant to the task. The third, exemplified by the Campione and Brown (1987) approach, operationalizes the zone of proximal development as a series of graduated prompts, predetermined on the basis of increasing explicitness in the teaching of the task. The fourth, described by Lidz (1991) is curriculum-based dynamic assessment that utilizes referral-relevant curriculum content and bases the intervention and interpretation on the degree of match between the process analysis of the demands of the task on the learner and the intactness of the processes the learner applies to the task. Most available specific procedures can be characterized in terms of one of these four models. While varying with the model, the information provided by dynamic assessment procedures can include in-depth descriptions of the strengths and weaknesses of the learner's cognitive processing, responsiveness of the learner to intervention, intensity of the effort required to facilitate change, and the linkage of assessment with intervention.

There are several books that provide a broad sample of available models and procedures of dynamic assessment from both American, Israeli, and European sources, as well as discussions regarding their applications. These include Carlson (1995), Gupta and Coxhead (1986), Hamers, Sijtsma, and Ruijssenaars (1993), Haywood and Tzuriel (1992), Lidz (1987, 1991), and Lidz and Elliott (2000). Reviews of research studies involving this approach are available in Lidz (1991, 1997).

DYNAMIC PSYCHOLOGY

The term *dynamic* relates to forces acting on a system. These forces include ongoing processes within the system as well as those external to the system. In psychology, *dynamics* relates to the interplay among motivating or driving forces that acts as a determinant of an organism's behavior. Thus, the term reflects a concern with the specification of motives and principles of motivated functioning. The term is also frequently associated with particular theories that emphasize the interplay among conscious and unconscious forces—drives, motives, needs, instincts, and wishes—in the direction of behavior. Such theories are known as psychoanalytic or psychodynamic theories of personality.

Theories of motivation are concerned, then, with specifying the motives characteristic of organisms and the principles of motive functioning that determine the initiation, maintenance, and termination of behavior.

Over the years a great variety of theories of motivation have been developed. These may be viewed as falling into three broad categories: (1) hedonic or pleasure theories; (2) cognitive or need-to-know theories; and (3) growth or actualization theories. A fourth category might also be noted that concerns the role of brain structures and neural mechanisms in motivated behavior. Research in this category typically is found in areas defined as psychobiology, biopsychology, or neurobiology.

Hedonic or Pleasure Theories of Motivation

Hedonic or pleasure theories form the largest category of theories of motivation. In one form or another, theories in this group emphasize the guiding role of pleasure in the organization of activity. A number of subclassifications within this category are possible. Perhaps the largest subgroup of hedonic theories consists of those that emphasize the organism's efforts toward *tension reduction.* Such theories emphasize the disquieting state of affairs caused by internal tension and the pleasure derived from the reduction of tension through the discharge of energy, expression of an instinct, or reduction in the level of a drive.

Woodworth took the concept of drive from the field of mechanics and viewed it as the source of motive power or force in organismic functioning. Thereafter, until the 1960s, this concept was used extensively by psychologists interested in human or animal behavior. Often distinctions were made between innate and acquired drives, primary and secondary drives, and viscerogenic and psychogenic drives.

In the area of animal behavior, the concept of drive played a major role in the learning theory of Clark L. Hull. According to Hull's stimulus-response (SR) theory, learning involves motivational variables such as drives. The organism has primary or innate drives such as pain and hunger, as well as learned or secondary drives such as the desire for money and fears—both learned during the course of development. Although the concept of drive referred to an internal process, it could be used by behaviorist-oriented psychologists because it was tied to specific external conditions manipulated by the experimenter. Variations in drive level, manipulated by the experimenter, were then related to objectively defined and measured overt responses.

Hull's work was extended by Miller and Dollard, among others. They made a particular contribution in emphasizing the role of learned, secondary drives in human behavior. For example, anxiety was viewed as a secondary drive based on the primary drive of pain. The anxiety drive is important because it can be learned quickly, become a strong motivating force, and lead to a variety of behaviors relevant to normal and abnormal behavior. Considerable attention was directed by Miller and Dollard to the relation between frustration and aggression, as well as to the importance of drive conflicts in clinical phenomena. Thus, the approach-avoidance conflict between two drives was viewed as the basic ingredient for the development of neurotic behavior. Dollard and Miller attempted to integrate the achievements of learning theory as expressed in the works of Hull with the achievements of psychoanalysis as expressed in the works of Freud.

A concept of motivation related to that of drive and used by many personality theorists is that of *need.* An important representative of such a view was Kurt Lewin, who viewed all behavior as driven by states of need or tension in the organism. As with Hull, needs could be primary and biologically determined or secondary and acquired through expe-

rience. Lewin viewed the existence of a need as leading to tension; it was a force that pushed the organism into action. The organism was viewed as a dynamic system in that ordinarily multiple needs enter into action. The forces associated with these needs have the qualities of strength, direction, and point of application.

The operation of these forces, in Lewin's view, takes place in a dynamic field where the state of any part of the field depends on and influences other parts of the field. The valence of objects, in association with states of organismic need or tension, pulls the organism in various directions and sets the stage for gratification, frustration, or conflict. Where multiple needs and environmental objects exist, the organism may experience an approach–approach conflict, an avoidance–avoidance conflict, or an approach–avoidance conflict.

Another representative of the hedonic, tension-reduction view was Henry Murray. The basic motivational concept in Murray's system was that of need. Needs could be primary and viscerogenic, or secondary and psychogenic, and represented forces for action. Murray distinguished between needs and traits in that needs represented a potential for action, whereas traits were defined in terms of actual behavior. Murray also attended to the role of environmental objects, suggesting that the environment could be defined in terms of press or characteristics associated with the potential for need gratification.

The concept of *incentive* is important, yet independent of its relation to drive theory, and forms a second subcategory of hedonic theories of motivation. In the incentive theories there is an emphasis on the association of stimuli with pleasure or pain and the goal-directed striving of the organism to achieve various outcomes. Thus, these theories are hedonic, like drive theories, in their emphasis on pleasure, but, unlike most drive theories, they emphasize the orientation of the organism toward future goals or end points. McDougall rejected a mechanistic, reflex, stimulus-determined view of behavior in favor of an emphasis on active strivings toward anticipated goals associated with pleasure.

Theories of motivation emphasizing goals often are criticized as being teleological. However, goals operate in the present in terms of mental representations of desired outcomes or end points. Most recently, the concept of goals has returned to play an important role in cognitive, information-processing models of human behavior.

A third variant of the hedonic model of motivation is that based on *affect*. Here the emphasis is on the organism's efforts to maximize pleasurable affect and minimize unpleasant affect, although there is no necessary association of affect with physiological need or drive. One of the early significant theorists to emphasize the role of emotion in motivation was P. T. Young. According to Young, stimuli (internal and external) acquire incentive value through their association with affective arousal, which is experienced primarily as positive or negative in nature. Through the gradual accumulation of experience, involving the association of various stimuli with affective arousal, the person develops a value system. Affective processes play the central role in organizing, activating, regulating, and sustaining learned patterns of behavior.

It is important to recognize an overlap among groups. Thus, for example, many drive theorists have emphasized the importance of affect; McDougall emphasized the role of affect in goal development, and many affect theorists emphasize the importance of affects in the development and maintenance of goal system functioning.

Cognitive or Need-to-Know Theories of Motivation

Indeed, by the 1950s, the concept of drive had almost been dropped entirely from the literature because of several reasons: problems in developing reliable measures of drives, particularly in humans; findings that did not support a tension-reduction point of view; and the growth of interest in information-processing theories associated with the cognitive revolution. In some ways, cognition replaced motivation as an important issue in the field. Some cognitive theories remained basically tension-reduction models.

Other cognitive theories, however, emphasized the motivation inherent in the information-processing activity of the organism. For example, J. M. Hunt, influenced by Jean Piaget, suggested that the organism always seeks to integrate new information with what is already known. Incoming information may be congruent or incongruent with what is known. Hunt cited evidence that incongruous or novel information instigates approach behavior, but, when the disparity between incoming and already stored information becomes too great, withdrawal behavior may also occur. Hunt not only emphasized intrinsic motivation but also suggested that differing degrees of incongruity between new and old information lead to various degrees of arousal and positive or negative hedonic tone. Thus, too little incongruity would be boring and too much would similarly lead to negative hedonic tone, whereas a moderate or optimum amount of incongruity would lead to a moderate degree of arousal, positive hedonic tone, and approach behavior. A cognitive model of motivation, then, was tied to a hedonic one.

George A. Kelly represents a theorist emphasizing a more purely cognitive theory of motivation. Kelly specifically rejected what he believed were the dominant "carrot and stick" theories of motivation—those emphasizing incentives that pulled the organism toward them and those emphasizing drives that pushed the organism. Instead, Kelly suggested that every person is a scientist seeking to gain better predictability concerning events. According to him, people are always active, so a theory of motivation does not have to account for activity per se. In terms of direction of movement, people choose to act in ways that promise the

greatest potential for elaboration of their construct system, thereby leading to enhanced prediction. People may experience negative affect in the sense of anxiety when they cannot predict events or experience threat when their entire construct (predictive) system is in danger. Furthermore, such negative affect will lead to corrective action.

The emphasis on cognition led many psychologists to be concerned with information processing in the absence of motivational considerations. To this day, work in the area of cognition, for the most part, remains disconnected from work in the areas of emotion and motivation.

Growth or Actualization Theories of Motivation

The third major theoretical approach emphasizes growth or actualization. Representative theorists include Andras Angyal, Kurt Goldstein, Abraham Maslow, and Carl Rogers. The common theme here is a rejection of the view that all human activity occurs in the service of tension reduction. Instead, there is an emphasis on activity stimulated by growth or self-fulfilling tendencies, and that may at times involve increases in tension. These theorists, often linked together as part of the human potential movement, generally do not reject the idea that some activity may occur in the service of reducing tension. However, the most important and basic striving of the organism is seen as directed toward actualizing and enhancing the experiencing organism. Maslow, for example, suggested a hierarchy of needs involving both biological needs (hunger, sleep, thirst) and psychological needs (self-esteem, affection, belongingness). When biological needs are satisfied, psychological needs predominate. In fact, however, psychological needs may even override biological needs in importance. Thus, Rogers suggests that the basic actualizing tendency is the only motive that needs to be postulated and that people are most human when functioning in relation to this motive. Although theories that are part of the human potential movement have been important in personality and were quite popular during the 1960s and 1970s, the concept of actualization has proven to be highly abstract and difficult to measure in any systematic way.

Psychoanalytic Theory

Finally, we can consider the specific theory most often linked with dynamic psychology—psychoanalytic theory. Psychoanalytic theory is dynamic in the sense that it emphasizes the importance of sexual and aggressive drives and the derivatives from these drives in human behavior. However, it also is a dynamic theory in its emphasis on the interplay among drives as expressed in concepts such as conflict, anxiety and the mechanisms of defense, cathexes and anticathexes, and compromise formations. According to such a view, the same phenomena may be the result of different combinations of forces, and a slight shift in energy may result in a dramatic alteration in the nature of the system.

Freud based his theory on the clinical phenomena presented to him by his patients and on the principles then current in biological science. Subsequent analytic theorists such as Alfred Adler and Carl Jung split with Freud over the nature of the fundamental motives in human behavior, although most held to a dynamic psychology in the sense of a system involving the interplay among motives or forces. Most recently there has been the beginning of an effort to focus on the clinical observations of Freud and to reformulate the theory in terms that are less metatheoretical and less tied to what is now considered an outmoded energy point of view. Concepts such as cognitions, purposes, meaning, and action, rather than those of instinct, drive, force, and energy, are emphasized.

General Systems Theory

Having considered various theories of motivation, we may turn to the broadest meaning of the term *dynamic* as found in general systems theory. Originally developed in biology and associated with Ludwig von Bertalanffy, general systems theory represents an effort to formulate principles of functioning that are characteristic of all biological systems. A system consists of interconnecting parts or units, the action of one having implications for the actions of others, whereas certain processes are characteristic of the whole. General systems theory distinguishes between open systems engaged in continuous exchanges with the environment and closed systems unaffected by external forces. Also, a distinction is made between living systems, which are open systems capable of regeneration and growth, and nonliving systems, which may be either open or closed, but which are not capable of regeneration or growth.

Certain concepts and principles are seen as being useful in the understanding of all living systems. Such concepts and principles in particular relate to the dynamic aspects of organismic functioning. For example, the concept of *feedback* emphasizes the ability of the organism to make use of information resulting from its own actions. Associated with this is an emphasis on the purposive or goal-directed aspects of organismic functioning, in particular the process of *adaptation.* Finally, in relation to the goal-directed quality of behavior, there is the concept of *equifinality*—the potential for the same goal or end point to be reached through multiple paths or means.

The dynamic aspects of general systems theory may be seen in its emphasis on ongoing processes within the organism and between the organism and its external environment. However, it does not tell us about the specific forces acting on the organism or the principles under which such forces operate. In terms of the more specific meaning of the term *dynamic,* general systems theory tells us little about the motives that instigate and direct action.

Conclusion

The emphasis here has been on dynamic psychology as it relates to human behavior and in particular to personality theory. However, it is important to recognize that concern with problems of motivation exists in the areas of brain research, physiological psychology, and animal psychology (ethology) as well. Particularly in the latter, concern has increasingly focused on the interplay among motives rather than on the operation of single motives, and on the organization of behavioral processes over time rather than on the specific factors that determine behavior at a specific moment in time. It is processes such as these that general systems theory has tried to capture and that lie at the heart of a dynamic psychology.

DYSPLASIA

The clinical term *dysplasia* has been used to describe a variety of anomalies in normal brain development that are associated commonly with mild to severe cognitive impairments and epilepsy. *Dysplasias* are best defined as microscopic abnormalities in brain cytoarchitecture. These abnormalities can be focal, for example, ectopias and heterotopias which appear as islands within an otherwise normal brain, or general, for example, lissencephaly or micro- or macrogyria, which affect large portions of the brain, if not the entire brain.

With few exceptions, dysplasias have been associated with anomalies in the cerebral or the cerebellar cortex. This association may reflect, in part, the fact that dysplasias are detected more easily in these two brain structures rather than a paucity of dysplasias in other brain regions. The cerebral cortex and cerebellum share a well-delineated stratified cytoarchitecture that results from a complex developmental history. Classically, neural development is divided into three major stages: neurogenesis (cell proliferation), neuronal migration, and neuronal maturation (including differentiation and synapse formation). In the development of both the cerebral and the cerebellar cortex, young neurons must migrate through layers of previously generated neurons before they begin differentiating and forming synaptic connections. During the migration phase, there are a number of developmental cues that occur between neuronal populations. After migration, neurons differentiate into cells with distinct shapes and synaptic connections. In both the cerebral and the cerebellar cortex, the stages of neuronal development are precisely timed and are delicately sensitive to disruption. The dysplasias discussed here result primarily from perturbations in normal neuronal migration and neuronal maturation that lead to malformations in the architecture of cerebral and cerebellar cortex. It is also possible, however, that particular neuronal groups migrate or mature at abnormal times because they were generated aberrantly.

In dysplasias that result from *abnormal neuronal migration,* small groups of neurons or entire populations may fail to migrate past previously generated neurons. Alternatively, the neurons may move defectively past their normal locations into regions of white matter, for example, into the cortical molecular layer. In the cerebellum, the failure of granule cells to migrate through Purkinje neurons will lead to malformations in cerebellar cytoarchitecture, as well as abnormal Purkinje cell development. Such dysplasias can affect motor coordination, as well as some aspects of learning and memory. In the cerebral cortex, focal migrational defects appear to disrupt local synaptic circuitry, in particular inhibitory circuitry, and are regarded as a predominant cause of early onset epilepsy. In humans, multiple focal ectopias in the cerebral cortex that result from altered neuronal migration are associated with developmental dyslexia. Migrational abnormalities are often compounded by alterations in neuronal generation and/or neuronal maturation, making it impossible to correlate specific behavioral abnormalities with a particular stage of development. In rodent and other primate studies, however, migrational abnormalities disrupt synaptic connectivity and produce cognitive abnormalities that correlate roughly with the magnitude of the cytoarchitectural abnormalities. Thus, cortical abnormalities that affect larger portions of cortex, such as micro- and macrogyria, ordinarily have more profound behavioral consequences than small focal anomalies.

Abnormal neuronal maturation, despite normal migration, is frequently the source of dysplasias that can lead to profound developmental disabilities, including mental retardation. Examples include genetic disorders, such as Down syndrome and Rett syndrome, as well as many unclassified amentias. In these dysplasias, entire brain regions fail to elaborate normally shaped dendritic trees and spines and display altered synaptic densities. Alterations in cortical dendritic length and number of spines have been reported in postmortem tissue from individuals with Down syndrome, a developmental disorder that almost invariably is associated with cognitive deficits. In recent years, with the advent of in vivo imaging techniques, dysplasias can be studied in living individuals and correlated more directly with behavioral changes. Increases in the width of the cerebral cortex in autism and fragile-X syndrome, as well as decreases in width of cortex in Down syndrome, have been observed. These findings strengthen the hypothesis that abnormal cortical morphology underlies some of the abnormal cognitive behaviors seen in these developmental disabilities. These changes in cortical widths likely reflect alterations in neuropil (dendrites and synapses) or glia cell populations and presumably lead to alterations in synaptic

connections within cortex and between cortical and subcortical regions.

The causes for morphological changes leading to dysplasias are only partially understood. Migrational abnormalities may be the consequence of altered cell-cell interactions but can also result secondarily from radiation exposure. Altered cell-cell interactions can be caused either by mutations in the genes coding for cell surface proteins or by environmental factors that change the expression of cell surface proteins. Neuronal differentiation is controlled by a plethora of factors including cell surface interactions, neurotrophins, cytokines, neurotransmitters and neuromodulators, and, last but not least, synaptic activity. Disruptions of any one, or any combination, of these factors may induce altered neuronal maturation. In addition to genetic mutations, aberrant neuronal migration and maturation may be caused by environmental factors, such as heavy metals (for example, lead); ethanol and other psychoactive drugs of abuse; or gestational and perinatal insults, such as hypoxia and ischemia.

DYSTHYMIC DISORDER

Dysthymic Disorder is a form of mood disorder that is characterized by mild, chronic depression. The current diagnostic criteria for dysthymia require chronic depressed mood (i.e., depressed most of the day, for more days than not, for at least 2 years). In addition, the individual must experience at least two of the following six depressive symptoms: low self-esteem, feelings of hopelessness, low energy or fatigue, difficulty concentrating or making decisions, sleep disturbance (insomnia or sleeping too much), and appetite disturbance (poor appetite or overeating). The symptoms must be persistent (i.e., the individual is never without depressive symptoms for more than 2 months at a time during this period), have a gradual (or insidious) onset, and cause significant distress or impairment in social or occupational functioning. Finally, the diagnosis cannot be made if the individual has a psychotic or bipolar (manic-depressive) disorder, or if the symptoms are due to medication, substances of abuse, or a general medical condition (*Diagnostic and Statistical Manual of Mental Disorders,* third edition, revised [*DSM-III-R*]; American Psychiatric Association, 1987).

Dysthymic disorder is closely related to the diagnosis of Major Depressive Disorder. However, episodes of major depression tend to be more severe, have a more rapid (or acute) onset, and are not generally chronic.

Dysthymic Disorder is relatively common, with approximately 3% of adults in the community meeting criteria during the past 12 months, and 6% meeting criteria at some point in their lives (Kessler et al., 1997). Like many forms of depression, dysthymia is approximately twice as common in women as in men. It is evident in all age groups (Kovacs, Akiskal, Gatsonis, & Parrone, 1994). Persons with an onset of dysthymia in childhood or adolescence are more likely to have other co-occurring psychiatric disorders and a greater family history of Mood Disorders than individuals with an adult onset.

Dysthymic Disorder frequently co-occurs (or is comorbid) with other psychiatric disorders. Approximately 75% of persons with dysthymia experience episodes of major depression that are superimposed on the preexisting Dysthymic Disorder. This pattern has been referred to as *double depression* (Keller, Lavori, Endicott, Coryell, & Klerman, 1983). Although this term implies that such individuals suffer from two different kinds of Depressive Disorders, it is likely that it is a single disorder that waxes and wanes, often in response to stress. Persons with dysthymia also frequently experience Anxiety Disorders, Substance Abuse Disorders, and Personality Disorders (particularly Borderline and Avoidant Personality Disorders).

As dysthymia is, by definition, a chronic condition, it is not surprising that recovery rates are low. In naturalistic follow-up studies (in which there is no attempt to control treatment), approximately 50% of outpatients with dysthymia recover (defined as having no or almost no symptoms for at least 2 consecutive months) during the course of the next 5 years. Approximately 50% of patients who recover experience a relapse, meeting full criteria for another episode of dysthymia within the next 5 years (Klein, Schwartz, Rose, & Leader, 2000).

Dysthymic Disorder runs in families, along with major depression. Persons with dysthymia have increased rates of both dysthymia and major depression in their first-degree relatives. There also appears to be a higher rate of some Personality Disorders in the families of persons with dysthymia (Klein et al., 1995).

Few studies have been conducted to distinguish the role of genetic from environmental factors in the familial transmission of Dysthymic Disorder. However, there is evidence that persons with dysthymia are more likely to have grown up in adverse early home environments, with increased rates of physical and sexual abuse and poor parenting (Lizardi et al., 1995). Although there is a large literature on the biological, psychological, and social variables that may be involved in the etiology and development of major depression, much less is known about the role that these variables play in dysthymia.

There are a number of studies indicating that dysthymic disorder is responsive to most types of antidepressant medication (Thase et al., 1996). In addition, several studies have indicated that maintenance treatment (i.e., continuing on medication after recovery) for dysthymia and double depression can reduce the risk of recurrences (Kocsis et al., 1996).

Various forms of psychotherapy are also used to treat Dysthymic Disorder. Although there are few controlled trials, there is preliminary evidence suggesting that several forms of psychotherapy, including cognitive therapy and interpersonal therapy, may also be effective in treating dysthymia and double depression (Markowitz, 1995). Moreover, a recent study indicates that in double depression the combination of medication and psychotherapy is more effective than either pharmacotherapy or psychotherapy alone (Keller et al., 2000).

E

EARLY CHILDHOOD DEVELOPMENT

Childhood is a culturally defined period in human development between infancy and adulthood, and, in historical perspective, it is a relatively recent social construction. Only in the past 400 years or so has the idea of childhood been a part of Western culture, with the recognition of this special class of people and special phase in the growth of each individual (French historian Philippe Aries analyzes the emergence of these ideas in *Centuries of Childhood*). Early childhood, as a special and important subperiod of childhood, most often refers to the months and years between infancy and school age or middle childhood: age 2 to 5 years.

These preschool years, sometimes extended to include infancy and toddlerhood or even lengthened into middle childhood to about age 8 years, are a time of significant and complex advances and reorganizations in behavior, and thus they figure centrally in most theories of human development. Learning, perception, reasoning, memory, and social relations undergo important changes and progressions in early childhood.

Many complex milestones and achievements have been described by numerous researchers. Gesell and his colleagues described the steps of development across domains, including physical growth, motor behavior, adaptive responsiveness, language, and personal/social behavior in their classic book *The First Five Years of Life.* Language is among the most impressive achievements in early childhood as the infant's babbling transforms itself into the very sophisticated language of the youngster at age 5. White describes the physical, emotional, and intellectual growth of preschool children in *The First Three Years of Life.* Similarly, other authors have described the equally remarkable complex of behavioral development and reorganization between ages 5 and 7.

Psychoanalytic developmental psychology posits early childhood as the critical period in development during which major personality orientations emerge that will continue into childhood, adolescence, and adulthood, forming boundaries and constraints on later modifications of intrapsychic organization, interpersonal relationships, and ego development. A person's sense of self and his or her gender identity are formed during this period of development. Freud's theory of psychosexual development describing the oral, anal, and phallic/Oedipal phases of early childhood development, and Erikson's theory of psychosocial development describing the tasks and crises of early childhood—trust versus mistrust, autonomy versus shame and doubt, initiative versus guilt, industry versus inferiority—are among the most influential psychoanalytic contributions toward understanding early childhood development. Bowlby's theory of attachment, further elaborated by Ainsworth, Harlow, and others, applies Erikson's theory to the special relationship between parent or primary caregiver and the developing child. These writers suggest that successful negotiation of the early parent-child relationship has lifelong implications for successful personality development, interpersonal relationships, and mental well-being.

In addition to learning to get along with others, a young child must learn to regulate his or her own behavior. Self-regulation refers to the capacity to monitor and direct one's activities in order to achieve goals or meet demands imposed by others. Self-control is the ability to regulate oneself even when the caregiver is absent, and may be considered a sign of emerging moral development. Learning to use a toilet and refraining from grabbing toys are examples of emerging self-regulation and self-control skills.

Cognitive developmental theories espoused by the Swiss psychologist Jean Piaget and his followers (Piaget & Inhelder, 1969) also emphasize early childhood development as a period of major steps in a child's construction of reality and knowledge. The infant in the sensorimotor stage of intelligence develops knowledge of self and the world through a complex series of interactions with the environment that emphasize sensory and motor experience. In early childhood the child achieves preoperational and then concrete operational thinking. With the increase in a child's capacity for imaginative and logical thought, important levels of symbolic and representational thinking develop as a basis for classification and categorization of information, essential to appreciation of important rules about the physical and interpersonal world. Recent controversies regarding the validity of children's memories of either traumatic or routine events are partly based on Piaget's descriptions of the limitations in reasoning skills during this stage of development and subsequent extensions of his theory.

Changes in family structure in the United States have dramatically altered the way many young children are raised. Mothers of young children are more likely to work outside the home for a variety of reasons, and both mothers and fathers are working longer hours. Although some laypeople worry about the long-term implications of exten-

sive out-of-home care during early childhood, accumulating evidence suggests that good, high-quality day care with appropriate ratios of staff to children can actually enhance some aspects of cognitive and social development. Increasing awareness of the influence of diverse family structures and multicultural family contexts for the multivariate processes of early childhood development characterizes contemporary research and practice.

The theoretical centrality of early childhood as a critical period in human development is applied in early childhood education and intervention. Great teachers and theorists such as J. A. Comenius (1592–1670), Jean-Jacques Rousseau (1712–1778), J. H. Pestalozi (1746–1827), Friedrich Froebel (1782–1852), John Dewey (1859–1952), Maria Montessori (1870–1952), and Anna Freud (1895–1982) long ago recognized the importance of learning and development in early childhood. Nursery schools, kindergartens, and early intervention programs such as Headstart are manifestations of an appreciation of early childhood development, not only in education and psychology, but also in social reform and public policy. With increases in the number of children and the number of hours spent in structured day-care settings, opportunities to observe and apply the knowledge gleaned from the study of early child development have expanded in the past two decades.

EAST-WEST PSYCHOLOGY

East-West psychology is a term used to describe the integration of Eastern or Oriental religions, philosophical disciplines, and psychological practices with Western psychological theory and practice. Confucianism, Taoism, Hinduism, Buddhism, and Islam are among the approaches included in the Eastern tradition. The Western psychological tradition includes the major psychoanalytic, behavioral, and humanistic theories.

The inquiry includes some states that go beyond limits of the ego and personality levels as defined in traditional Western psychology, such as ordinary and altered states of consciousness, meta- or optimal health, self-actualization and human potential, and the full range of human existence and development.

Boundaries of Western Psychology

The West has basically derived its understanding of phenomena from an intellectual and objective approach. In the classical Greek concept, the universe was viewed as comprehensible by reductionism, divisible, static, nonrelativistic, and atomistic. As defined in the philosophy of Descartes, matter and spirit are seen as being fundamentally different.

Roger Walsh and others ("Paradigms in Collision") described the different levels and aims of psychotherapeutic intervention as (1) traditionally therapeutic—reducing pathology and enhancing adjustment; (2) existential—confronting the questions and problems of existence; and (3) soteriological—enlightenment, transcendence of the problems first confronted at the existential level. He said that Western psychologies and therapies focus on the first two levels, while the third is the chief goal of the consciousness disciplines that incorporate Eastern thought.

Western psychology recognized distortions of reality as pathological but equated "reality" with the world as perceived in the waking state of awareness and perceived the self as separate from what is perceived. Daniel Goleman stated that this viewpoint denied access or credibility to reality as perceived in other states of consciousness.

Carl Jung, whose investigation of psychology included Eastern religions, began to widen understanding of the unconscious to incorporate a collective dimension common to all cultures and races. In asserting the existence of "impersonal" levels of consciousness, he took a step beyond former reductionistic and mechanistic theories. Jung commented on the boundaries of Western psychology when he said, "Western consciousness is by no means the only kind of consciousness there is; it is an historically conditioned and geographically limited factor, and representative of only one part of mankind."

The Eastern Perspective

The Eastern worldview is dynamic and organic, seeing the cosmos as one inseparable reality, spirit and material at the same time.

According to the Eastern orientation, the usual state of consciousness is an illusory distortion of perception (maya) arising from a dualistic distinction between subject and object, between self and the other, and between the organism and the environment.

The aim of Eastern practices is to penetrate the veil of the accustomed reality and emerge into an awakened state or enlightenment. It is possible to transcend ego conflicts, view ego demands with detachment, and understand human experience in the light of an awakened state of mind.

Buddhist teachings indicate the necessity of freeing oneself from the analytic mind, from all conditioning and compulsive functioning of the mind and body, and from habitual emotional responses. These teachings discuss developing awareness in terms of fractions of a second, to awaken people to the fleeting glimpses of an open, precognitive spaciousness that occur before things are interpreted in a particular perspective. Gaps in the stream of thought permit a direct experience of pure awareness that, according to the Buddhist perspective, is the individual's true nature.

Eastern tradition has emphasized a personal, empirical approach to knowledge different from the Western path of scientific, impersonal, objective knowledge. As opposed to analytic and logical thinking, direct experiential knowledge is stressed.

In the Eastern tradition, the contemplative-meditative mode of knowing has been valued as accurate, whereas traditional Western science and philosophy have used only sensation-empirical and cognition-conceptual modes.

Meditation is one of the primary practices in the East for shifting away from the active, linear mode and toward the receptive and process-oriented mode. Meditation serves to dismantle the automatism and selectivity of ordinary awareness.

Emergence of East-West Psychology

As mental health professionals felt more and more limited by the theories of behaviorism and psychoanalysis, which were mainly derived from studies of psychopathology, and ignored certain areas—such as value, will, and consciousness—necessary for a full inquiry into human nature, humanistic psychology emerged in the 1960s as a model based on health and the whole person. Humanistic psychology recognized the individual's drive toward self-actualization and the ways in which this idea could be fostered in individuals, groups, and organizations.

Western science in the twentieth century found that the classical concept of reductionism and an atomistic divisible universe were inadequate as explanation. Modern theoretical physics has adopted a model of the universe that is holistic, indivisible, interconnected, and dynamic, unlike the former reductionistic and static view, and supports the findings of mystical insight. This view is consistent with and supportive of the emergence of East-West psychology.

Western psychology was compelled to encompass a broader scope by the development in the culture at large of the human potential movement, cross-cultural exposure, disillusionment with the materialistic dream, and the use of psychedelic drugs and technologies for the induction of higher states of consciousness. This scope incorporated these experiences and values, which were domains already explored and described in Eastern thought.

Technological advances have permitted researchers to describe the physiological and biochemical correlates of altered states of consciousness. As mental health professionals have individually and collectively been influenced and affected by their contact with Eastern philosophy, they have synthesized this awareness into their own theory and practice of psychology.

The evidence of this synthesis was seen in the development of transpersonal psychology, documented by the publication of its first journal in 1969. A. Maslow foresaw as a fourth force of psychology a psychology that would be "transpersonal, transhuman, centered in the cosmos rather than in human needs and interest, going beyond humanness, identity, self-actualization, and the like." Transpersonal psychology is conceived of as promoting and facilitating growth and as expanding awareness beyond limits prescribed by most traditional Western models of mental health.

The transpersonal psychology movement brought together insights from other traditions and from modern depth psychology, and validated and influenced an emerging paradigm that incorporated a health- rather than disease-oriented model, transcendence rather than adjustment focus, and a transpersonal rather than a personality-level approach.

In the field of health care and health psychology, disciplines from the East have been incorporated into traditional Western medicine and health care delivery. Research in biofeedback has expanded the scope of behavioral and physiological psychology.

As a specific method of training the mind, increasing awareness, and directing human attention, meditation has gained widespread recognition in the areas of personal growth, health, and stress management. It is estimated that by 1980 more than 6 million people in the United States alone had learned some form of meditation. Clinically, meditation is being taught as a tool for stress reduction, control of addiction, and increased coping ability.

Educational psychology has been influenced by the awareness that both hemispheres of the brain must be stimulated and that the development of creativity, imagery, and fantasy through the receptive mode is as important as the development of logic and reasoning in the active mode.

Susan F. Wallock

EDUCATIONAL MAINSTREAMING AND INCLUSION

Early advocacy for mainstreaming in education has become increasingly focused on inclusion, with frequent confusion

and failure to distinguish between the two ideas. Although at times the terms are used synonymously, *mainstreaming* refers most frequently to the return of children from special education to regular education, and *inclusion* refers to meeting the needs of children within the regular classroom setting without assignment to a special education setting. In the case of the use of support services, inclusion implies the provision of services within the classroom or on a consultative basis to the teacher ("push in"), in contrast to "pull out" approaches, which typically involve removal of children from the classroom for involvement in specialized support services. Both mainstreaming and inclusion reflect the federal mandates concerning placement of children with special needs in the "least restrictive" environment (IDEA, PL101-476, Sec. 612 (5)(B)).

Inclusion has been most strongly advocated for children with mild handicapping, but it has been viewed by some as appropriate for children with moderate to severe disabilities as well. The meaning of inclusion may vary from full to part time, and from applying to some or all children with disabilities. The move toward mainstreaming was given impetus by the landmark article by Dunn in 1968, and the move toward inclusion was catalyzed by the Regular Education Initiative proposed by Madeleine Will (e.g., 1986).

The success of students with disabilities in regular education relies to a great extent upon introduction of a number of curriculum modifications and supports within the classroom. Classroom size and the degree of disruptiveness and depth of need of the included students are likely to affect the success of inclusion as well. Mere proximity of handicapped and nonhandicapped children does not result in a successful mainstreaming experience (Guralnick, Connor, Hammond, Gottman, & Kinnish, 1996; Zigmond & Baker, 1990). The evidence suggests that children need to interact in order to modify their attitudes toward peers with disabilities (Voeltz, 1980; Weinberg, 1978). Teachers need to intervene both personally and programmatically to promote inclusion, and to do so effectively requires supportive consultative services and training experiences.

Teachers need staff development opportunities, consultative support, and in-class help in order to address the needs of these students (Johnson & Cartwright, 1979; Naor & Milgram, 1980). The attitudes of teachers toward mainstreaming appear to reflect their feelings regarding their ability to succeed in teaching students with special needs, and their success in this requires adequate support services (Galis & Tanner, 1995; Larrivee & Cook, 1979).

Evidence regarding the effectiveness of inclusion depends upon the population and the nature of the variables studied. Baker, Wang, & Walberg (1995) conducted a meta-analysis documenting small to moderate positive effects for children with special needs in favor of inclusion, with no significant negative effects on students without disabilities. The effectiveness of inclusion as an educational intervention remains to be seen and may in fact vary, depending upon the student and the attitudes, experience, and practices of the teaching and support staff (Galis & Tanner, 1995). Parents and educators, as well as individuals with disabilities, seem to have very different points of view about their preferences for settings (Vaughn & Klingner, 1998). The most valid conclusion appears to be that assignments to educational treatments and settings needs to be carried out in a highly individualistic way that takes into consideration evidence of effectiveness, the needs of the learner, and the preferences of the family and student.

EFFECTIVE COMPONENTS OF PSYCHOTHERAPY

All forms of psychotherapy, by and large, are followed by more benefit in more people than is informal help or the

simple passage of time. This strongly suggests that, despite the clamor of conflicting claims by different therapeutic schools and their doctrinal and procedural differences, all must share certain therapeutic features—features, moreover, that distinguish psychotherapies from other forms of help from friends, relatives, or others.

Three major distinguishing features can be noted: (1) the helper is a professional; (2) the proceedings are confidential; and (3) the therapy is grounded in a theory that "explains" the patient's distress and prescribes certain procedures for alleviating it. In addition, the therapeutic medium of all psychotherapies is symbolic communication, usually by words but sometimes by exercises and other bodily rituals that have a large symbolic component.

The forms of distress and disability assumed to be amenable to psychotherapy share significant psychological components. These range from emotional states exacerbating chronic illnesses to psychoses, but most patients in psychotherapy suffer primarily from so-called neurotic symptoms such as anxiety, depression, phobias, and obsessions. The specific aim of all forms of psychotherapy is to relieve symptoms, but this invariably includes implicitly strengthening patients' self-esteem, improving their coping strategies, and the like.

The Demoralization Hypothesis

Since all forms of psychotherapy are helpful, their shared features must counteract a type of distress and disability common to most seekers of psychotherapy. This condition may be termed *demoralization*—a sense of incompetence based on inability to solve some internal conflict or external problem, coupled with feelings of distress. Why some persons are more prone to demoralization than others is largely unknown. Inborn characteristics such as lack of stamina or hardihood probably have much to do with it, as does the extent of support from others.

An empirical definition of demoralization has been provided by the following list of complaints, scales of which a series of population surveys found to be as highly correlated as the probable error of each scale permitted: poor self-esteem, hopelessness/helplessness, dread (including fear of insanity), confused thinking, sadness, anxiety, psychophysiological symptoms, and perceived physical health. These include the most frequent complaints of patients in psychotherapy.

Except possibly for some phobias, some depressions, and obesity, no convincing evidence has emerged that one therapeutic approach is more successful overall than any other. A plausible hypothesis, then, is that patients seek therapy because of both demoralization and specific symptoms. Although both patients and therapists believe the aims of therapy to be relief of symptoms, successful therapy in fact counteracts the patient's demoralization, and this is the main source of benefit.

From the standpoint of the demoralization hypothesis, patients' complaints can be grouped into three classes. The first and most common are direct expressions of demoralization, notably anxiety and depression. They are also the most responsive to any therapeutic intervention. Second are symptoms related to pathologic organic processes such as cyclical depressions, hallucinations, delusions, and the like. Demoralization may often play an etiological role in these, because stressing the patient readily exacerbates them.

The final group includes so-called neurotic symptoms such as phobias, compulsions, obsessions, amnesias, and the like, currently believed to be symbolic self-perpetuating and self-defeating efforts to solve internal conflicts or persistent difficulties with others resulting from distorted perceptions of self and others. Their origin is customarily attributed to deficient or damaging learning experiences in early childhood.

Shared Features of All Psychotherapies That Counteract Demoralization

All therapies combat demoralization by seeking to counteract patients' feelings of discouragement, isolation, loss of self-confidence, and feelings of failure. Morale-enhancing features of all psychotherapies can be divided into those inherent in the therapist-patient relationship and the therapeutic setting, and those related to the processes of therapy.

Therapist-Patient Relationship

At the most general level, demoralization is combatted by the therapist's being a professional in the broadest sense of the term—the possessor of an expertise either recognized by society as a whole (as in the case of psychologists, psychiatrists, and social workers) or acknowledged by a group whose values are shared by the patient.

Furthermore, as a professional the therapist is expected to assume some responsibility for the patient's welfare, and the therapist's professional status reassures the patient that the therapist will not exploit the patient and that the patient need not fear that what he or she says or does will disrupt the therapeutic relationship through angering, seducing, or otherwise causing the therapist to abandon the professional role. The therapist counteracts demoralization by conveying continuing willingness to listen to and respect the patient.

By accepting the patient for treatment, the therapist implies that the therapist believes the patient can be helped. This in itself inspires the patient's hope—an emotion that powerfully counteracts demoralization and is often probably healing in itself. Arousal of hope at the first therapeutic contact may account in large part for the large proportion of outpatients (60 to 80%) who improve significantly after one interview. The therapist also provides a consistent outlook, value system, and standards of behavior that help the patient to reduce confusion.

In addition to these general therapeutic features of the patient-therapist relationship, the therapist may influence the patient in specific ways through the therapeutic procedure. However "nondirective" the procedure may seem to be, patients tend to follow therapists' leads, even when therapists are not aware of giving any. The influencing power of therapists rests on the patients' dependence on them for help, intensified by the patients' concern about the therapists' opinion of them. *Evaluation apprehension,* as it has been termed, has been shown to heighten a person's susceptibility to influence.

Therapeutic Setting

A private office or a clinic conveys the atmosphere of a place of healing. Because what occurs in therapy is confidential—that is, confined to the therapeutic setting—the patient is free to reveal thoughts, feelings, and attitudes, including shameful or repressed aspects of the self, without fear of consequences beyond the therapeutic situation. Thus, the setting in itself facilitates morale-enhancing experiences such as increased self-awareness and the relief following revelation of information or exploration of personal problems that the patient fears mentioning in settings of daily life.

Morale-Enhancing Aspects of the Therapeutic Process

Emotional Arousal

Although the reason is unclear, clinical experience indicates that beneficial change in the patient is facilitated by the emotional arousal accompanying therapy. This arousal may be caused by feelings toward the therapist; by reexperiencing repressed feelings toward self and family; in behavior therapies, by attempting to change habitual behaviors; by particular maneuvers to elicit strong emotions; or in other ways.

Cognitive and Experiential Learning

All therapies convey new information by helping patients to bring to awareness hitherto unavailable knowledge about themselves. To be most effective, these discoveries must provide a new emotional experience.

As models, guides, and advisors, all psychotherapists provide the patient with a variety of opportunities for learning better ways of coping with problems. By the type of questions asked, the therapist offers a model of rational decision making, including consideration of alternatives before acting.

Enhancement of the Sense of Self-Efficacy

Patients in psychotherapy typically believe themselves to be more or less at the mercy of inner feelings or external stresses. This state of mind is coupled with a sense of failure, as well as dysphoric emotions that further reduce the patient's coping capacity. Thus, strengthening the patient's sense of mastery or self-efficacy is probably the strongest morale-enhancing component of all psychotherapies. To this end, all therapies typically emphasize that therapeutic gains result primarily from the patient's own efforts.

Implications of the Demoralization Hypothesis for Training

The likelihood that all psychotherapeutic procedures are followed by essentially similar overall improvement rates should not be taken to imply that training of therapists is unnecessary. Therapeutic skill may be compared to musical talent: Not everyone can be a virtuoso, but—except for the few who are tone-deaf—anyone can learn to play an instrument and improve with practice. Similarly, mastery of one or more procedures maintains the therapist's own sense of competence and thereby the patient's faith in the therapist—states of mind crucial for the success of all therapies. The feeling of competence also sustains the therapist's self-confidence in the face of the inevitable failures experienced by practitioners of all therapeutic schools. Finally, only through persistent, expert application of specific therapies can any hitherto undiscovered beneficial effects be discovered for different clinical conditions or personality types.

Ideally, then, training programs should teach several forms of therapy, so the student can pick those that are most congenial. The more a therapist can master, the better; but in any case the therapist can rest assured that, for most if not all patients, the chosen method will not be less effective than alternative approaches.

EFFECTIVENESS OF PSYCHOTHERAPY, EFFICACY OF PSYCHOTHERAPY

Scientific Evaluation of Psychotherapy

Two methods have been utilized to conduct scientific evaluations of psychotherapy. Efficacy and effectiveness research are both important and provide us with distinct information about how psychotherapy works. Although both methods are used, to date, efficacy studies have dominated the field. As a result, most of what we know about how well psychotherapy works comes from efficacy rather than effectiveness research.

Efficacy studies test psychotherapy in a controlled experimental design and typically utilize a structured, man-

ualized session format delivered over a fixed number of sessions. Patients are selected carefully, with the bulk carrying single, uncomplicated diagnoses, falling into specific age ranges, and meeting other strict inclusion and exclusion criteria. Patients are randomly assigned to different treatments, and ideally the treatment being studied is also compared to a placebo control. The strict design in efficacy studies provides strong internal validity and thereby enables researchers to be confident that the treatment under investigation causes the observed effect. However, because of the tightly controlled format, efficacy studies are associated with weaker external validity, suggesting that obtained findings may not generalize to the clinical populations for whom they are ultimately intended.

Effectiveness studies, by contrast, evaluate the outcome of therapy directly on clinical populations, but in doing so sacrifice the rigors of efficacy research. Effectiveness research is conducted as it is actually delivered in a variety of settings, including hospitals, clinics, and private practice. Patients are heterogeneous, typically have multiple diagnoses, and may or may not be randomly assigned to treatment groups. The choice of treatments or therapists is often determined by patients themselves, manuals are typically not utilized, and the length of treatment is not fixed. Treatment is usually terminated once the therapist or patient determines that progress has occurred or as a function of insurance constraints. As a result, effectiveness research, although not as internally rigorous as efficacy research, provides us with information about how well treatment works when it is carried out in clinical practice.

Efficacy Research on Psychotherapy

Comprehensive reviews have been undertaken of psychotherapies with demonstrated efficacy in controlled studies (e.g., Chambless et al., 1998; Nathan & Gorman, 1998; Weissman, Markowitz, & Klerman, 2000). Chambless and Ollendick (2001) recently completed the most extensive review of the efforts of eight work groups (from the United States, United Kingdom, and Canada) focused on identifying psychotherapies with existing efficacy data or evidence-based treatments (EBT). Although the criteria used to define EBTs were not the same for each work group, overall the criteria used tended to be conservative. For a treatment to be defined as evidence-based, support from at least one rigorous randomized clinical trial was necessary. Based upon Chambless and Ollendick's (2001) "review of reviews" it is accurate to say that at least one EBT (and sometimes several) exists for the full spectrum of psychiatric disorders, including the following (see Chambless & Ollendick, 2001, for complete list):

Anxiety and Stress
Agoraphobia/Panic with Agoraphobia
Blood injury phobia
Generalized Anxiety Disorder
Geriatric anxiety and depression
Obsessive-Compulsive Disorder
Panic Disorder
Posttraumatic Stress Disorder
Public speaking anxiety
Social Anxiety Disorder (Social Phobia)
Specific Phobia
Chemical Abuse and Dependence
Alcohol Abuse and Dependence
Benzodiazepine withdrawal
Cocaine Abuse
Opiate Dependence
Bipolar disorder
Major Depressive Disorder
Anorexia Nervosa
Binge-Eating Disorder
Borderline Personality Disorder
Bulimia Nervosa
Chronic pain
Irritable-bowel syndrome
Marital discord
Migraine headache
Obesity
Schizophrenia
Smoking cessation
Sexual dysfunction

Psychotherapies are not efficacious for all conditions (for example, interpersonal psychotherapy (IPT) has been shown to be ineffective in two studies with opiate abusers). However, for several disorders, psychotherapies have been shown to be as effective as psychotropic interventions (e.g., cognitive-behavioral therapy [CBT] for Panic Disorder, CBT and IPT for Bulimia Nervosa). For other disorders, psychotherapy is an invaluable adjunct to medication (e.g., bipolar disorder, Schizophrenia).

In this section we highlight data on the efficacy of psychotherapies for three commonly occurring psychiatric disorders.

Depression. Both IPT (Weissman et al., 1979; Elkin et al., 1989) and CBT (cf. Glaoguen, Cottraux, & Cucherat, 1998; Elkin et al., 1989) have been shown to be as effective as psychotropic medication for the treatment of depression (Depression Guideline Panel, 1993) and have also demonstrated efficacy in decreasing relapse and recurrences in depression (Frank et al., 1990; Jarrett, Basco, & Ritter, 1998; see Sanderson & McGinn, 2001, for a comprehensive review). An amalgam of the two (cognitive-behavioral analysis system of psychotherapy) has demonstrated efficacy in treating chronic depression (Keller et al., 2000).

Anxiety Disorders. A considerable body of evidence has shown that CBT is as effective as, or more effective than, medications in the treatment of the full range of anxiety disorders (cf. Nathan & Gorman, 1998, for a comprehensive review), Agoraphobia (e.g., Chambless, Foa, Groves, & Goldstein, 1979), Generalized Anxiety Disorder (e.g., Barlow, Rapee, & Brown, 1992), Obsessive-Compulsive Disorder (e.g., Fals-Stewart, Marks, & Schafer, 1993), Panic Disorder (e.g., Barlow, Gorman, Shear, & Woods, 2000), Social Phobia (e.g., Heimberg et al., 1998), and Posttraumatic Stress Disorder (e.g., Foa, Rothbaum, Riggs, & Murdock, 1991).

Schizophrenia. Efficacy studies for Schizophrenia focus on relapse prevention and typically compare two or more psychotherapies in patients also receiving antipsychotic medication. Overall, when compared to treatment as usual, behavioral, supportive, and systems-based family therapies and social skills training have demonstrated efficacy in reducing relapse in Schizophrenia (e.g., Falloon et al., 1984; Hogarty, Anderson, & Reiss, 1986; Leff, Kuipers, Berkowitz, & Sturgeon, 1985; Schooler et al., 1997). The different family-based interventions appear to be equivalent to each other (Baucom, Shoham, Mueser, Daiuto, & Stickle, 1998; Brent et al., 1997) except that family therapy utilizing insight-oriented techniques and focusing on the past has not demonstrated efficacy in reducing relapse (Kottgen, Sonnichsen, Mollenhauer, & Jurth, 1984) and can be associated with negative outcomes (McFarlane, Link, Dushay, Marchal, & Crilly, 1995).

Effectiveness. The next challenge is determining how well these treatments generalize to clinical practice, where patients often do not have a single diagnosis, where practitioners in the community must be used, and where training programs must be simple and cost-efficient (effectiveness research). Although effectiveness research is in its infancy, the existing data generated thus far support the use of EBTs in clinical practice (Wade, Treat, & Stuart, 1998; Sanderson, Raue, & Wetzler, 1998; Franklin, Abramowitz, Kozac, Levitt, & Foa, 2000; Tuschen-Caffier, Pook, & Frank, 2001; Antonuccio, Thomas, & Danton, 1997; Otto, Pollack, & Maki, 2000).

EFFERENT

Axons leaving the neuronal soma are often referred to as *efferents*. The observations made on the efferents of alpha spinal motoneurons have contributed to our understanding of motor control. In natural recruitment of motoneurons, Ohm's law applies, so neurons with the smallest-diameter somas are recruited first. In contrast, electrical stimulation of a mixed peripheral nerve results in the largest diameter axons being activated at the lowest threshold, that is, first if stimulation current is gradually increased. The diameters of the largest-diameter axons of alpha motoneurons are similar to those of Ia afferents, although the largest of the latter are usually slightly larger than the largest motoneuronal axons.

M Waves in EMG from Motoneuronal Axon Stimulation

When motoneuronal axons are stimulated, an M wave results in the electromyogram (EMG) after the brief interval required for nerve conduction from the stimulus site to the muscle electrodes. This wave appears before the H-reflex waveforms that result from stimulating Ia afferents, as the effects of the latter must be exerted over a longer path, through the synapse with motoneurons in the spinal cord (Brooke et al., 1997). The constancy of M wave magnitudes is used as a biocalibration of the stability of stimulating Ia axons in reflex studies. The technique works because of the similarity in diameter of these efferents and afferents. Using this technique Misiaszek, Cheng, and Brooke (1995) showed that passive movement-induced attenuation of H-reflexes occurred over all stimulus strengths, from that at the threshold for M waves to that eliciting Mmax. It was inferred that the same afferent group, probably Ia, was involved in the expression of the reflex over the range of stimulation.

The M wave is the orthodromic outcome of stimulating motoneuronal axons. However, there is also an antidromic action potential set up at that time. This poten-

tial may collide with antidromically proceeding motoneuronal action potentials resulting from H-reflex activation. Accordingly, as M wave magnitudes rise, H-reflex magnitudes diminish. A further nuance results when alpha motoneuronal action potentials for voluntary movement are occurring. Then, (1) M waves may be diminished due to refractory motoneuronal axons; (2) H-reflexes may be diminished due to antidromic activation of alpha efferents and/or to refractory motoneurons; and (3) H-reflexes or M waves may be maximized under a recently-cleared-line principle. Thus, a contraction and high stimulus intensity to elicit Mmax results in distributions of M wave and H-reflex magnitudes that range from zero to maximal (Brooke & McIlroy, 1985). It is noteworthy that with normal stimulus recruitment curves, the maximal H-reflexes obtained seem to actually be maximal, as the collision technique described in the previous sentence does not appear to produce any larger H-reflexes. This collision technique has the potential to describe the ongoing ebb and flow of temporal recruitment of motoneurons over time.

Clinical Evaluation Using Efferent Stimulation

M waves are used for assessment of the number of motor units in a muscle and thus for estimation of the number of alpha motoneurons serving a muscle (the motoneuronal pool for that muscle). When the intensity of transcutaneous electrical stimulation of a mixed nerve is gradually increased, a current is reached at which the first small M wave is seen at the appropriate latency in the EMG. This M wave represents the muscular result of activation of the axon of a motoneuron. If the current is then gradually increased, at a certain point the M wave will become larger and its shape will alter. The muscular response to the activation response of a second motoneuron has been added to the first. This process and identification in the M wave shape can be continued for a number of motoneurons. If the current is reduced, the M wave decreases in discreet steps. At a high current, the maximum M wave is obtained, and further increases in current elicit no further increase in M wave magnitude. These phenomena have been combined by McComas and colleagues (McComas, 1996) to estimate the number of motoneurons in a pool. The mean M wave magnitude (mV) from a small sample of early recruited motoneurons is divided into the magnitude of Mmax (mV), the result being the estimate of the number of motoneurons serving the muscle. The procedure is now computerized. The technique has revealed the very large losses of motoneurons with advanced aging and during diseases such as amyotrophic lateral sclerosis (McComas, 1996).

F waves in the EMG are used to establish motoneuronal integrity (Ma & Liveson, 1983). With high intensities of transcutaneous stimulation of motoneuronal efferents, antidromic activation can produce action potentials that, arising from the soma, course orthodromically back down the axon to lead eventually to excitation of the muscle fibers. These F waves have latencies very similar to H-reflexes. Separation from H-reflexes usually relies on the high variability in being able to produce F waves, compared to H-reflexes, and the high stimulation intensity required for the former compared to the latter. Morphological differences in wave forms of reflex and F wave may also help.

Completeness of maximum voluntary contraction can be established using the sequelae of Mmax stimulation. If a patient is not making a maximum voluntary contraction when requested, the Mmax stimulation will still produce a muscle twitch (McComas, 1996).

In some diseases, such as myasthenia gravis, the adequacy of release of acetylcholine (the neurotransmitter at the myoneuronal junction) is compromised. In diagnosing this deficiency, it is common to test with a series of four or five Mmax stimuli closely spaced in time (interstimulus rate can range from 3 to 50Hz; Walton, 1987). The later stimuli in the time series result in markedly reduced M waves in the EMG in the patient with transmitter deficiency, compared to the healthy person. This contrasts with the availability of glutamate at the Ia-motoneuronal synapse. In the latter case, even as few as two closely spaced stimuli will result in the second H-reflex being much reduced in magnitude or even nonexistent. This is the phenomenon of homosynaptic depression (Capek & Esplin, 1977).

EGO DEVELOPMENT

The term *ego development* is used in different ways by different authors. Most psychoanalysts use it in one of three ways: (1) to describe the period of formation of the self or ego in the first 2 or 3 years of life; (2) to describe the development of all ego functions, including what Heinz Hartmann called the "conflict-free ego sphere," that is, locomotion, speech, and so on; (3) to describe aspects of ego development such as those described by Erik Erikson as psychosocial tasks, entwined with psychosexual development (i.e., the development of drives and drive derivatives) and tied to age-specific life tasks. In clinical psychoanalytic use, disorders of ego development usually refer to problems arising in the period of ego formation; they are likely to lead to profound maladjustment or to "borderline" personality types.

Psychologists have delineated a different conception that has roots in Harry Stack Sullivan's *interpersonal theory of psychiatry.* This conception, in addition to being a developmental sequence, is a dimension of individual differences that applies in principle at any age, although higher stages are never found in early childhood and the lowest stages are rare in maturity. Terms such as *moral development, interpersonal reliability,* and *cognitive complexity* have been used for aspects of the sequence.

Stages

The earliest stage (or stages)—the *period of ego formation*—occurs in infancy. This stage is presocial, at first autistic, later symbiotic with the mother or mother figure. Acquisition of language is believed to be an important factor in bringing the period to an end.

The *impulsive stage* is next: The child confirms a separate existence from the mother by willfulness and is dependent on others for control of impulses. Persons at this stage are preoccupied with their own needs, often bodily ones, and see others as a source of supply. They live in a universe conceptually oversimplified, at least as to its interpersonal features. Rules are seen as specific prohibitions or as frustration of wishes rather than as a system of social regulation.

Growth at first is in terms of ensuring more certain gratification by tolerating some delay and detour, which leads to the *self-protective stage.* Children at this stage will often assert some degree of autonomy to free themselves from excessive dependence; however, their interpersonal relations remain exploitative. They are concerned with power and control, dominance and submission. In early childhood this period is normally negotiated with the help of rituals; when a person remains at this stage into adolescence and adult life, there may be a marked opportunism. Rules are understood but are manipulated to the person's advantage.

Normally in late childhood there is a sea-change. One identifies oneself and one's own welfare with that of the group. Rules are partly internalized and are adhered to precisely because they are group-accepted and endorsed. This is the *conformist stage,* which has been widely recognized and described as a personality type. Conformity is valued for its own sake, and people tend to perceive others and themselves as conforming.

Many people seem to advance beyond the conformist stage by perceiving that they themselves do not always live up to the high standards of conduct that society endorses and do not always have the approved emotions in some situations. This period is called the *conscientious-conformist level,* or the *self-aware level.* Whether it is a transition between the conformist stage and the conscientious stage or a true stage is an unsettled point. The person at this level sees multiple possibilities as appropriate.

At the *conscientious stage* rules are truly internalized. The person obeys rules not just because the group approves, but because they have been self-evaluated and accepted as personally valid. Interpersonal relations are understood in terms of feelings and motives rather than merely actions. The person has a richly differentiated inner life and—in place of stereotyped perceptions of others—a rich vocabulary of differentiated traits with which to describe people. Thus, their parents are described as real people with both virtues and failings, rather than as idealized portraits or as entirely hateful persons. Self-descriptions are also modulated; the person does not describe the self either as perfect or as worthless, but sees circumscribed faults that he or she aspires to improve. Achievement is valued, not purely as competitive or as social recognition, but as measured by the person's own standards. Persons at this stage may feel excessively responsible for shaping the lives of others.

In moving beyond the conscientious stage, the person begins to appreciate individuality for its own sake; thus this transitional level is called *individualistic.* It is characterized by increased conceptual complexity: Life is viewed in terms of many-faceted possibilities instead of diametrically opposed dichotomies. There is spontaneous interest in human development and an appreciation of psychological causation.

At the *autonomous stage* the characteristics of the individualistic level are developed further. The name *autonomous* is somewhat arbitrary, as are all the stage names. No aspect of behavior arises suddenly in one era and perishes immediately on passage to the next. What characterizes this stage particularly is respect for the autonomy of others. A crucial case is the subject's own children, especially acknowledging their right to make their own mistakes. The person at this stage is often aware of functioning differently in different roles. One copes with inner conflict such as that between one's own needs and duties. Conflict is viewed as an inevitable part of the human condition rather than as a failing of self, other family members, or society.

Beginning at the conscientious stage and especially

characteristic of higher stages is seeing oneself in a larger social context. This is particularly true of persons at the *integrated stage,* who are able to unite concern for society and for self in a single complex thought.

Related Domains

Many authors have sketched stages of development closely related to the foregoing sequence. Clyde Sullivan, Marguerite Q. Grant, and J. Douglas Grant refer to their stages as "interpersonal integration." Their conception has been used in studies of differential treatment of different subtypes of delinquents.

Kohlberg has developed a system of stages for the development of moral judgment; his ideas have been widely applied. In schools they have been the basis for curricula to encourage moral development, including the forming of alternative schools on the model of "just communities."

Selman labels his stages "interpersonal perspective taking." He has studied school-age children; thus his work applies chiefly to early stages. He has also studied a small clinical sample.

Perry's sequence corresponds to some of the higher stages. John M. Broughton covered a wide age range. He was concerned with development of "natural epistemologies"—conceptions of mind, self, reality, and knowledge.

Methods of Study

Although the idea of character development goes back at least to Socrates, modern study begins with Jean Piaget. Kohlberg, Selman, and others have adapted Piaget's method of clinical interviewing. Kohlberg presents his subjects with an unfinished story ending in a moral dilemma. When the subject finishes the story, there follows a probing interview during which reasons for choices are explored; the stage assigned depends on the reasoning. Rest has evolved an objectively scored test that is an adaptation of Kohlberg's instrument. Broughton and Perry have worked out interviews beginning with broad, unstructured questions.

Loevinger, Wessler, and Redmore's scoring manual for a sentence completion test is sufficiently detailed as to be semi-objective and includes self-teaching exercises. Marguerite Warren (formerly Grant) and others working with the interpersonal integration system of C. Sullivan and colleagues have used a variety of instruments including interviews, sentence completion tests, and objective tests.

Theories

There are two major theoretical issues: Why is the ego (or self) as stable as it is? How and why does it manage to change at all?

The theories of ego stability are all variations of H. S. Sullivan's "anxiety-gating" theory. What Sullivan calls the "self-system" acts as a kind of filter, template, or frame of reference for one's perception and conception of the interpersonal world. Any observations not consonant with one's current frame of reference cause anxiety. However, the main purpose of the self-system is to avoid or attenuate anxiety. Therefore, such perceptions are either distorted so as to fit the preexisting system or—in Sullivan's phrase—they are "selectively inattended to." Thus, the theory states that because the self-system or ego is a structure, it is self-perpetuating.

Kohlberg has a structural theory of change. When a person at one stage repeatedly encounters and grapples with reasoning and arguments just one stage higher, conditions are optimal for assimilating the reasoning and hence advancing toward that stage.

Identification is the key to the current psychoanalytic theory of ego development. One moves ahead in part because one identifies with some admired model who is (or is perceived as being) at a slightly higher level. Although Kohlberg's theory is primarily cognitive and the psychoanalytic theory is affective, both imply a Piagetian model of equilibrium, disequilibration, and re-equilibration. Both are, in effect, "social learning" theories, although they differ radically from what is usually called social learning theory.

There is another element in the psychoanalytic theory that originates as social learning but becomes wholly internal to the individual. The ideal or model toward which the person strives or aspires need not be embodied in the environment. The capacity for constructing one's own model is what is called the *ego ideal.*

Ausubel presents another theory of some aspects of ego development. Infants believe themselves to be omnipotent because their wishes are magically realized. (Here Ausubel is following Ferenczi's essay.) As children learn of their total dependence on their parents, they face a catastrophic loss of self-esteem. To escape that fate, they assign their former omnipotence to their parents and so become their satellites, shining in their reflected glory. In late childhood and early adolescence one should "desatellize," or learn to derive self-esteem from one's own achievements. Satellization and desatellization may miscarry at several points, resulting in various patterns of psychopathology.

Perry depicts many factors as contributing to both stability and change in the college years. His model of change has implications for a dynamic explanation. The student whose world view is, say, dualistic (right vs. wrong, us vs. them) at first learns to perceive some special field as more complicated and multiplistic (many possibilities, everyone has a right to his or her own opinion). As the fields of application for the multiplistic view increase, those where the dualistic view applies correspondingly shrink, until the multiplistic view becomes the predominant one, with only isolated areas of life still seen in dualistic terms. The same paradigm applies for the transition from multiplistic to relativistic thinking (some views are better because they are

grounded in better data or sounder reasoning). One of the generally accepted aims of a liberal education is to encourage acceptance of the relativistic nature of all knowledge. In Perry's view, relativism should be followed by acceptance of some commitments.

J. Loevinger

ELDER ABUSE AND NEGLECT

Of all the facets of gerontology, elder abuse and neglect is one of the least well understood. Even the definitions of abuse and neglect are debated and vary from locality to locality across the United States. Often the term *abuse* or *abuse and neglect* is used generically to refer to a variety of behaviors that are not strictly abuse or neglect (e.g., financial exploitation) or that do not involve a second party (e.g., self-neglect). Here the discussion will be restricted largely to the infliction of physical or emotional harm or serious threat of such harm on a vulnerable individual (abuse) or the withholding of needed care or attention from such an individual (neglect) by a second person or persons in a trust relationship that occurs in a domestic setting. Abuse and neglect occurring in institutional settings are not covered. Even abuse and neglect in domestic settings, some experts have argued, deserve separate treatment because they are very different—the former being a criminal justice matter and the latter a civil justice issue or even a health, mental health, or social service issue often stemming from some type of caregiving crisis. Both will be treated here as forms of elder mistreatment.

Numbers reflecting prevalence suggest the magnitude of abuse and neglect, while recent research suggesting substantially increased death rates among those mistreated reflects its seriousness. Although neither the prevalence nor the incidence of elder mistreatment in the United States is known with any precision, the best research suggests that 2–4% of the population 65 years and older suffer abuse or neglect.

Prevalence of abuse and neglect, it must be emphasized, is extremely difficult to measure. Not only are victims often reluctant to reveal mistreatment, especially by a relative, but also the "victim" as judged by legal standards or professional practice may not view himself or herself as a victim. Furthermore, perception of what constitutes mistreatment may differ markedly according to the cultural background of an individual. Moreover, mistreatment can flow both ways, or even emanate from the elder "victim," especially where an elder care recipient suffers from dementia and exhibits aggressive behavior.

Of all of the types of mistreatment, neglect appears to be the most prevalent, and emotional abuse almost certainly exceeds, in number of episodes, physical abuse of all types. Self-neglect, not covered here, may well be more prevalent than any type of mistreatment by a second party.

The second-party perpetrator is most likely a family member and, most often, an adult child or a spouse. Conceptually, elder mistreatment by a spouse that takes the form of abuse, at least, also can be considered domestic or intimate partner violence. However, it is rarely treated as such by governmental authorities or service providers, largely because the sociocultural and statutory histories of the domestic violence arena are very different from those that give rise to concerns surrounding elder abuse. The domestic or intimate partner violence rubric is almost always reserved for violence against women of childbearing age.

There is no want to the list of suggested explanations for elder mistreatment. Neglect is almost always diagnosed within the context of caregiving, and in that context it seems somewhat easier to explain than physical abuse. Physical or mental incapacity of the caregiver, and in some cases simple ignorance of the underlying needs of a frail elder or, more often, of appropriate ways to address those needs, seem adequate explanations. In perhaps a very substantial proportion of cases, the abuse or neglect that transpires reflects a poor emotional relationship between victim and perpetrator that, in many instances, may have a relatively long history.

Until at least the 1980s, caregiver stress was offered as the leading explanation for elder abuse and neglect, a sort of blame-the-victim approach. More recent studies, however, have cast doubt on that as the major explanatory factor, and scholars have turned largely from attempting simple explanations to focusing on the nature of the interaction or relationship between the victim and the perpetrator and on identifying risk factors for or indicators of mistreatment.

Being a victim of abuse or neglect in the past appears to be the single best predictor of future victimization. Beyond that, principal risk factors seem to be poor mental (and perhaps physical) functioning of the victim (both of which tend to be associated with advanced age); financial dependence of the abuser on the victim; poor emotional health of the perpetrator, including substance abuse; social isolation of the family; and, for married victims, a history of marital violence. Even on these factors, however, agreement is less than perfect.

The absence of consensus and the presence of disparate findings from research studies regarding explanations or risk factors for elder abuse and neglect undoubtedly reflect not only the complexity of human behavior overall but also the potential reality that the explanation or even the risk factor varies by type of mistreatment involved. Further complexity is added by the fact that each type does not necessarily occur in isolation but may be perpetrated in various combinations of mistreatment and exploitative behaviors.

Following the principle of assumed power of *parens patriae,* public responsibility in the United States for addressing elder mistreatment has devolved under federal mandate to the states. States have set up mechanisms (typically an abuse hot line) for reporting instances of elder mistreatment of any type (often including financial exploitation and self-neglect) as well as Adult Protective Services offices to investigate these reports. This reporting function has been modeled on that established earlier for reporting child abuse, and in many states reporting is mandatory for anyone who strongly suspects mistreatment has occurred. The service response to confirmed mistreatment cases typically is the provision of long-term care services, such as a homemaker or personal care, that were designed for cases of self-neglect. Due to budget constraints reflecting the add-on nature of services and infrastructure to deal with elder abuse and neglect existing in most states, however, these purportedly long-term care services are actually provided for a brief period of time, usually for only a few days or weeks until the immediate crisis is past. Moreover, in stark contrast to governmental actions taken to address domestic abuse or violence, the only public responsibility commonly assumed in the case of elder abuse is for the victim. Typically, the state takes little if any action with respect to the perpetrator other than perhaps Adult Protective Service investigators reporting to the police cases in which they suspect a crime has been committed. Criminal prosecution of elder abusers is rarely pursued.

Elder abuse and neglect or mistreatment is a complex phenomenon that has received too little research or public policy attention. As a consequence, our knowledge base surrounding it is rudimentary. Unfortunately, and in part also as a consequence, the intervention to address it typically is too narrow and, at the same time, too imprecise. This social problem calls for a multidisciplinary approach in research and a multispecialty approach to applying the results of that research in prevention, treatment, and adjudication.

ELECTRODERMAL ACTIVITY

Many who record electrodermal activity (EDA) today share the basic belief expressed by Carl Jung in 1907 and by some present-day lie detector operators that verbal responses do not tell all, but that EDA does reveal the secrets of "mental life."

The skin has a special significance because it both receives outside information and responds to signals from within. As one EDA investigator stated, "We can listen in on such signals by taking advantage of the fact that their arrival at the skin is heralded by measurable electrified changes that we call electrodermal activity." If we think of our skin as a giant receptor separating us from the rest of the world, is it any wonder that responses obtained from it would be of interest to psychologists? Today we think of EDA as a measure of the state of the organism's interaction with its environment. EDA reflects not only emotional responding; it is also elicited by cognitive activity.

Terminology

The terms used to describe EDA have changed over the years. The term used at the turn of the nineteenth century was *psychogalvanic reflex* (PGR). Later the term *galvanic skin response* (GSR) was used. Today most psychophysiologists have dropped this term in favor of *electrodermal activity* (EDA).

The electrical activity of the skin can be measured in two ways. First, a small current can be passed through the skin from an external source, and the resistance to the passage of current is then measured. This technique was first used by Feré in 1888 and is referred to as the *exosomatic method.* The second method, the *endosomatic technique,* was first used by Tarchanoff in 1889; it measures the electrical activity at the surface of the skin, with no externally imposed current. The exosomatic method has been modified today into the measurement of *skin conductance* (SC), the reciprocal of skin resistance. The endosomatic method is still used to measure skin potential (SP), but skin conductance recording is used today by most researchers.

When describing EDA, one can discuss basal activity (tonic) versus the response to a stimulus (phasic). When referring to tonic electrodermal activity, the convention is to use the word *level* (L) and when discussing phasic activity to use the word *response* (R). Therefore, the four common descriptions of electrodermal activity are as follows: skin conductance level (SCL), skin conductance response (SCR), skin potential level (SPL), and skin potential response (SPR).

Psychophysiological recordings show a third type of activity in addition to tonic and phasic activity. Spontaneous electrodermal activity appears in records obtained using both the SC and SP techniques.

Physiological Basis

We still don't know a great deal about the complex relationship of the central nervous system to EDA. Peripherally, we know that eccrine sweat glands, a special type of sweat gland, are intimately involved in EDA. Eccrine sweat glands are concentrated in the palms of the hands and soles of the feet. What makes them of particular interest to psychologists is that they respond primarily to "psychic" stimulation, whereas other sweat glands respond more to increases in temperature. The eccrine sweat glands are innervated by the sympathetic branch of the autonomic nervous system, but the chemical transmitter at the post-

ganglionic synapse is acetylcholine, not noradrenaline, as would be expected in the sympathetic nervous system.

The eccrine sweat glands, which can be thought of as tiny tubes with their openings at the surface of the skin, act as variable resistors wired in parallel. Depending upon the degree of sympathetic activation, sweat rises toward the surface of the skin in varying amounts and in varying numbers of sweat glands. The higher the sweat rises in a given gland, the lower the resistance in that variable resistor. In some cases, but certainly not all, sweat overflows onto the surface of the skin. This hydration of the skin with salty sweat increases SCL and SPL. Years ago, it was thought that EDA was determined solely by the amount of sweat on the surface of the skin. We now know this is not so. Even in those cases where stimulation does not result in sweat at the surface of the skin, changes in EDA are often found, because even a slight rise of the sweat in the glands will change the values of the variable resistors. If we wished to quantify the EDA at a given moment, we would sum the values of all the active resistors that are wired in parallel. The sum of resistors in parallel equals the sum of their reciprocals, or conductance. This is one reason for using skin conductance rather than skin resistance when describing exosomatic EDA. A second reason is that skin conductance, unlike skin resistance, does not have to be corrected for base level. In addition to the hydration of the skin and the number of active sweat glands, other factors that may be involved in EDA include a membrane in the sweat duct wall that affects the reabsorption of sweat, and changes in pressure in the duct that affect the opening of the pores in the skin. For skin potential, it has been demonstrated that SPL of extremely relaxed subjects is determined largely by the concentration of potassium at the surface.

Factors to Control When Recording or Interpreting EDA Data

The following subject variables have been found to affect EDA: age, sex, race, and stage of menstrual cycle. Environmental factors that effect EDA include temperature, humidity, time of day, day of week, and season.

EMOTIONAL CONTAGION

Emotional contagion has been defined as "The tendency to automatically mimic and synchronize expressions, vocalizations, postures, and movements with those of another person and, consequently, to converge emotionally" (Hatfield, Cacioppo, & Rapson, 1993). The Emotional Contagion Scale is designed to measure the extent to which men and women tend to catch expressions of joy, love, anger, fear, and sadness in others.

Theoretically, emotions can be caught in a variety of ways. Some researchers have argued that conscious reasoning, analysis, and imagination account for the phenomenon. Others contend that people must *learn* to share others' emotions. Most, however, assume that emotional contagion is an even more primitive process—that it happens automatically, outside of conscious awareness.

The process of emotional contagion is thought to operate like this:

> *Proposition 1:* In conversation, people automatically and continuously mimic and synchronize their facial expressions, voices, postures, movements, and instrumental behaviors with those of others.
> *Proposition 2:* Subjective emotional experience is affected moment to moment by the feedback from such mimicry/synchrony.

Theoretically, emotional experience could be influenced by (1) the central nervous system commands that direct such mimicry/synchrony in the first place; (2) the afferent feedback from such facial, verbal, or postural mimicry/synchrony; or (3) conscious self-perception processes, wherein individuals draw inferences about their own emotional states on the basis of the emotional expressions and behaviors evoked in them by the emotional states of others.

> *Proposition 3:* Consequently, people tend, from moment to moment, to "catch" others' emotions.

Researchers have collected considerable evidence in support of these propositions.

Proposition 1

Researchers have found evidence that people do tend to imitate the facial expressions, postures, voices, and instrumental behaviors of others.

Social psychophysiologists find that people are capable of mimicking others' emotional expressions (as measured by electromyographic [EMG] procedures) with surprising speed and accuracy. When people observe happy facial expressions, they show increased muscular activity over the zygomaticus major (cheek) muscle region. When they observe angry facial expressions, they show increased muscular activity over the corrugator supercilli (brow) muscle region.

Such mimicry begins almost at birth. Developmental psychologists find that 10-week-old infants imitate their mothers' facial expressions of happiness, sadness, and anger. Mothers mimic their infants' expressions of emotion as well.

There also is voluminous evidence that people mimic and synchronize their vocal utterances. Communication re-

searchers find that there is interspeaker influence on utterance durations, speech rate, latencies of response, and a host of other speech characteristics. People also tend to mimic and synchronize their postures and movements with others.

Proposition 2

Researchers have found that emotions are tempered to some extent by somatic and skeletal feedback.

Researchers interested in testing the facial feedback hypothesis have employed a variety of strategies for inducing people to adopt various emotional expressions. Sometimes they simply ask them to fake an emotional expression. Sometimes they ask them to exaggerate or to hide any emotional reactions they may have. Sometimes they try to trick them into adopting various facial expressions. Sometimes they try to arrange things so they will unconsciously mimic others' emotional and facial expressions.

In all cases, however, scientists have found that people's subjective emotional experiences *are* affected by feedback from the facial expressions they adopt.

Scientists have assembled an impressive array of evidence supporting the proposition that people's subjective emotional experiences are affected, moment to moment, by feedback from facial, vocal, postural, and movement mimicry.

Proposition 3

Researchers from a variety of disciplines provide evidence that emotional contagion exists. The majority of work has come from animal researchers; child psychologists interested in primitive emotional contagion, empathy, and sympathy; clinicians exploring the process of transference and countertransference; social psychologists; and historians.

Individual Differences

Do people differ in the capacity to share the joy, love, sadness, fear, and anger of others? It seems that they do. Theorists have proposed a variety of characteristics that may increase individuals' susceptibility to emotional contagion. Scientists contend that people are more likely to catch others' emotions if they are attentive to others' feelings; if they feel closely linked to others; if they are skilled at reading facial expressions, voices, and gestures; if they tend to mimic others' facial, vocal, and postural expressions; if they are sensitive to their own emotions; and if they are emotionally expressive. Conversely, people who rarely attend to others, who construe themselves as distinct and unique from others, who are unable to read others' emotions, who fail to mimic, or whose subjective emotional experiences are unaltered by peripheral feedback should be fairly resistant to contagion.

Researchers also propose that people should be most vulnerable to contagion in certain kinds of *relationships.* Caretakers and infants should be especially prone to share one another's emotions. Men and women ought to be more likely to catch one another's emotions when they are passionately or companionately in love and when they possess similar attitudes and beliefs. People who have power over others should be resistant to contagion. Those they control should be more vulnerable to soaking up emotions.

As yet, however, there is only sparse evidence in favor of these reasonable-sounding hypotheses.

Implications

Cognitive psychologists have discovered that people are able to use multiple means to gain information about others' cognitive and emotional states. Conscious analytic skills can assist people in figuring out what makes other people "tick." But if people pay careful attention to the emotions they experience in the company of others, they may well gain an extra edge into "feeling themselves into" others' cognitive and emotional states, as well.

There is evidence that both what people think and what they feel may provide valuable, and different, information about others. In one study, for example, researchers found that people's conscious assessments of what others must be feeling were heavily influenced by what the others *claimed* to feel. People's own emotions, however, were more influenced by the others' nonverbal clues as to what the others were *really* feeling.

EMOTIONAL DEVELOPMENT

Emotions play a significant role in the development of the child. Not only are they central to the process of attachment and other social interactions, but they also influence how well a child does in other developmental domains. This brief review discusses developmental theories of emotion and the developmental course of specific emotions. As the child matures, he or she gains new perspectives on how emotions are used. These processes are reviewed here.

Although there are several different perspectives on the development of emotion, the two that dominate the literature differ as to the mechanisms by which emotions emerge. The evolutionary/functionalist developmental theory (Dar-

win, 1872/1965; Izard & Malatesta, 1987; Barrett & Campos, 1987) proposes that emotions emerge when they are adaptive. The cognitive theory of emotional development (Lewis, 1993), on the other hand, suggests that emotions emerge or differentiate depending upon the development of certain cognitive skills. Interestingly, these mechanisms often converge.

At birth, the infant is capable of feeling distress, disgust, pain, and interest, although there is debate as to whether interest is an emotion. By 3 months of age, when the infant perceives and differentiates familiar from unfamiliar persons, he or she expresses happiness or joy. Smiling functions to maintain social contact. At approximately the same time, when the infant begins to self-initiate reaching and grasping, anger emerges. Anger is an emotion generated when an obstacle (barrier) prevents the child from obtaining a goal (interesting toy) and thus motivates the child to remove the obstacle. When the infant begins to move out into the environment on his or her own, usually at around 7 to 9 months of age, a new emotion emerges that serves to protect the infant from new and potentially dangerous persons and objects—fear. This emotion is often reflected in the infant's newfound avoidance of strangers; however, not all infants exhibit what is often called stranger anxiety.

Emotions such as embarrassment, shame, pride, guilt, and empathy are proposed to emerge after the development of self-awareness. Self-recognition, which emerges between the ages of 18 and 24 months, has been shown to be a necessary condition for embarrassment. Self-conscious emotions such as pride and guilt require the child to evaluate his or her own behavior against a standard. This ability occurs around the 2-year age mark.

Toddlers and preschoolers undergo significant progress in all areas of development, particularly with respect to the emotional domain. Component skills of emotional development include the expression, understanding, and regulation of emotion (Denham, 1998).

Emotional expression involves the communication of nonverbal emotional signals in appropriate contexts and in socially appropriate ways. Expression of an emotion may be characterized by its intensity, duration, and frequency. The complexity of the emotions expressed, the knowledge of the appropriate emotion for a given situation, and the cultural rules for displaying a given emotion in a social situation are a result of within-person differences, as well as interpersonal interactions that contribute to the child's abilities. By 3 years of age, children are able to interpret others' emotions correctly. Five- and 6-year-olds are also very capable of assessing the events likely to have caused another's emotional state. The complexity of children's understanding of *display rules,* the culture rules that suggest when it might be best to mask or substitute a felt emotion for prosocial reasons, is difficult to untangle. However, these skills appear to develop rapidly in preschoolers and school-age children, and girls appear to assimilate these rules into their repertoire sooner than boys.

Emotion regulation is the complex process of appropriately coping with positive and negative emotions and the situations that elicit these emotions. The regulatory or coping process may occur at the level of the emotion, the perceptions or cognitions about the emotion, or the behavior associated with the emotion. Even very young babies are capable of modulating their emotions to some extent, for example, by sucking on their fingers. In early childhood, competence in emotion regulation is marked by the gradual shift from external sources of regulation, such as parents, to internal sources of regulation. They learn strategies to reduce emotionally charged information, such as thinking of something pleasant, looking away, or reinterpreting the event.

The abilities to label emotions, including the more complex emotions, understand the causes and consequences of emotion and emotional situations, discern the independence of one's own emotions from others' emotional experience, and communicate with others about emotion are all aspects of *emotion understanding.* Children gather this important information as they increasingly interact with others and find themselves with the opportunity to label or relate to another person's emotion. Each of these interrelated emotional skills is intricately associated with social development, as emotional competence is vital in understanding one's own experiences and negotiating successful interactions with others.

These skills are not traits that young children simply develop at specified time points; rather, their development is the result of interactions that socialize the child over time. Conversations and interactions with parents, other caregivers, siblings, and peers assist children's development of an understanding of emotion. These interactions are embedded within the larger cultural context, which also exerts a socializing force (Saarni, 1999). Three mechanisms proposed in the process of emotion socialization are modeling, coaching, and contingency (Halberstadt, 1991). *Modeling* occurs whenever someone expresses an emotion and it is witnessed or observed by the child in context. When modeling occurs, it contributes to the overall emotional climate of any family or social group. *Coaching* of emotions includes any talk or teaching about emotions and their consequences. For example, talk about emotion in the family is an important vehicle for teaching young children about emotions in themselves and others, and dealing with emotionally charged events (Dunn & Brown, 1991; Dunn, Bretherton, & Munn, 1987). *Contingency* includes others' emotional and behavioral reactions to a child's emotions. These reactions may increase or decrease the likelihood of the child's patterns of expressiveness and the coping styles they use for handling emotions on their own (Halberstadt, 1991). The complexities of the process of emotion socialization are many. The individual characteristics of the parent and the child, and the child's age, sex, and siblings, are just some of the many factors that may influence this essential but complicated developmental process.

EMPIRICISM

Empiricism is one of several rival doctrines in the philosophical field of epistemology, the study of knowledge. Epistemology's main concern is how to establish the truth of knowledge claims. If someone advances a proposition or group of propositions—for example, a scientific theory—how are we to determine that it is true? Empiricism holds that knowledge arises from and is to be justified by perceptual experience. Although empiricism seems straightforward enough, it faces challenges that have created its epistemological competitors.

Plato offered the first influential critique of experience as the basis for knowledge claims, pointing out that experience is frequently mistaken. If one person enters a room from a blizzard and another enters it having stoked a fire, they will disagree about whether the room is hot or cold. Perception is a source only of opinions, of beliefs that might be true or false. Knowledge, Plato said, must be absolutely and demonstrably true for all times and all places. Plato advanced two important alternatives to empiricism: rationalism and nativism. Rationalism locates the truth of knowledge claims in logic. Plato was influenced by Pythagoras and his followers, who created the notion of logical proof. When one works through the proof of the Pythagorean theorem, for example, one arrives at a truth that cannot be doubted because it has been formally proved. Mathematical proofs derive their authority from reason, not experience, and Plato hoped to extend a similar level of provable certainty to all knowledge claims.

Plato was also influenced by the Eastern religions infiltrating Greece from the fifth century B.C.E. onward. These religions taught that humans had immortal souls; some taught that a soul went through a cycle of reincarnations. Plato taught that, while out of the body, the soul sees eternal, transcendental Forms, heavenly prototypes of the objects of ordinary experience. Thus, a cat is a cat because it resembles the Form of the Cat, while a dog resembles the Form of the Dog. Knowledge of the Forms remains latent in the soul upon reincarnation and is merely awakened by perceptual experience. In Plato's philosophy, right use of reason makes knowledge demonstrably true, while existence of the Forms makes knowledge true eternally and transcendentally.

Plato's student Aristotle defended the validity of experience. He advanced a version of perceptual realism, asserting that we perceive things as they really are. Error arises from mistaken judgments we make about our experience, not from experience itself. Seeing a man on the street, one might mistake him for a friend, but the error impugns the viewer's judgment, not his or her perception. In a broad sense, Aristotle was an empiricist because he said that knowledge arises from experience; but in the modern sense, he was not an empiricist because he did not share its representational theory of perception.

Modern empiricism in philosophy and psychology began with Locke and Descartes. Because of Descartes' emphasis on reason and his belief in innate ideas he is typically lumped together with Plato as a rationalist and nativist, but his theory of perception is also the starting point for modern empiricism as developed by Locke. Descartes proposed that we do not experience the world directly, but through a veil of ideas that represent objects. In this representational theory of perception, one does not directly perceive the book he or she is now reading (as Aristotle taught), but only a representation of it, an idea held in consciousness. Locke's empiricism held that knowledge is the mind's acquaintance with its ideas.

Unfortunately, representational empiricism runs up against the problem that, because one does not perceive things directly, one cannot be certain—cannot *know*—that one's ideas are, in fact, accurate copies of things outside consciousness, raising the possibility that the world is very

different than it seems to be, or even that the external world is a dream or hallucination. In the 17th and 18th centuries, different philosophers responded to the shortcomings of empiricism in different ways. Hume developed the skeptical possibilities in empiricism, concluding that knowledge is, in fact, never provably true, thus anticipating the American philosophy of pragmatism. Other Scottish philosophers attempted to revive realism and a new form of nativism. They taught that God endowed us with mental powers—faculties—enabling us to perceive and know His creation as it really is.

Perceptual realism, however, remained a minority viewpoint, surfacing in the philosophy of Brentano and American Neorealism and in Gestalt and Gibson's ecological theory of perception. Nativism was slain by evolution—that is, innate ideas and faculties, if they exist at all, are implanted not by God but by the vagaries of natural selection. In psychology, nativism has returned in Noam Chomsky's linguistics and in evolutionary psychology, but researchers in these fields seek in the genes, not truth, only certain mental dispositions we inherit from our hominine ancestors.

Empiricism became and remains the dominant epistemology in Great Britain and in the United States. The most important alternative to empiricism, idealism, arose with Kant, and it exerted great influence in nineteenth- and early twentieth-century Germany. Kant was shocked by Hume's conclusion that all knowledge claims are fallible, and he attempted to synthesize empiricism and rationalism into an epistemology more worldly than the former but more certain than the latter. Kant thought of science as the paradigm of human knowledge and acknowledged that it begins with and systematizes experience. However, Kant held that human experience is shaped by logically necessary (not God-given) characteristics of the human mind, which yield the orderly phenomena studied by science. Science therefore rests on a rationally provable foundation that is inherent in the mind and therefore exists prior to experience. Kantian idealism affected the psychology of Jean Piaget, who proposed that formal logical structures of the mind determine how children and adults perceive and think about the world.

EMPLOYEE ASSISTANCE PROGRAMS

Employee assistance programs (EAPs) are workplace programs offered by employers to employees that assist troubled employees and their family members with a variety of issues, ranging from financial and legal concerns to mental health and substance abuse problems. EAPs traditionally focus on these problems as they affect workplace performance, but EAPs are broadening their focus with the rise in managed care. The EAP movement in the United States grew out of industrial alcohol programs in the 1950s and saw its biggest growth during the 1980s. It was during the 1980s that most EAPs moved from primarily alcohol-focused programs to the multi-issue or broad-brush programs that they are today.

EAPs offer a broad array of services to employees and their family members to assist with their problems. Comprehensive EAPs engage in identification, assessment, motivation, referral, short-term counseling, monitoring, and follow-up activities and help with a variety of personal problems, including family, emotional, financial, legal, and substance abuse concerns. EAPs do not provide long-term treatment or health care services. Several attempts have been made to determine a core set of services, or technologies, that define an EAP. The traditional core technologies of EAPs were defined by Paul Roman and Terry Blum in the late 1980s and early 1990s as the following seven activities:

1. Identify employee behavioral problems based on workplace performance concerns.
2. Provide consultation to supervisors, managers, and union representatives on how to use and refer employees to the EAP.
3. Use constructive confrontation strategies when appropriate.
4. Create micro-linkages with treatment, counseling, and community resources.
5. Create and maintain macro-linkages between the work site and treatment, counseling, and community resources.
6. Focus on employee alcohol and substance abuse problems as a strategy that offers the most promise for recovery and cost savings to the work site.
7. Serve as a consultant to the work site on personal problems affecting employee welfare.

Recently, changes to these traditional core technologies have been proposed by various authors to better match the current role of EAPs in the workplace. Attempts at defining a new set of core technologies have been hampered, however, by the ever-changing role of EAPs. Many EAPs now serve as behavioral health care gatekeepers for managed care plans, further complicating efforts to define a core set of EAP services.

Regardless of core services, EAPs fall into two primary types: internal and external. Internal EAPs are owned by the sponsoring employer, and EAP staff members are company employees. Internal EAPs can be housed at the work site but often have separate offices to increase the perception of confidentiality and independence from company management. External EAPs are separate companies that the employer contracts with to provide EAP services. Ex-

ternal EAPs may have on-site representatives, but these representatives are not company employees. Both internal and external EAPs typically offer assessment and referral, but internal EAPs are more likely to offer counseling services. Early on, most EAPs were internal EAPs that evolved from other workplace programs, often through the efforts of a single dedicated employee. More recently, however, large external EAPs have begun to dominate the industry. These EAPs often have affiliate networks that include small providers that service specific employers.

Several studies have attempted to assess the prevalence of EAPs. In the late 1980s, the Bureau of Labor Statistics (BLS) conducted a survey of employer antidrug programs, including EAPs. The BLS estimated that approximately 31% of U.S. employees had EAP services available to them. These employees were concentrated within large work sites, however. Seventy-six percent of establishments with more than 1,000 employees had EAPs, while only 9% of establishments with fewer than 50 employees had EAPs. Two surveys conducted by the Research Triangle Institute (RTI) in the mid-1990s showed that the prevalence of EAPs had grown substantially since the BLS survey. By 1996, EAPs reached well over half of the U.S. workforce, but EAPs were still concentrated within large work sites. Much of the growth in EAPs occurred in external providers, with external EAPs providing approximately 81% of EAP services in 1993. More recently, a benefit survey by the Society for Human Resource Management showed that EAP growth has continued through today. Estimates suggest that EAPs are one of the most common employee benefits. Only dental plans, life insurance, and health-related insurance and managed care plans exceed the coverage of EAPs.

Estimates of the extent to which employees use EAP services when they are available are less common than estimates of the prevalence of EAPs. Anecdotal evidence and research conducted at individual work sites suggest that approximately 5–12% of employees use EAP services annually. Evidence suggests that EAP utilization is slightly lower among females and among minorities, possibly because of confidentiality concerns but also due in part to EAPs' traditional focus on workplace rather than family issues. To date, however, no nationally representative survey has attempted to estimate the rate at which employees use EAP services or examine differences in utilization rates by demographic groups.

Cost estimates of EAP service, which are most often presented as the cost per eligible employee, suggest that EAPs are an affordable workplace program in most cases. The RTI surveys found that in 1993 the cost of EAP services ranged from about $18 per eligible employee for external EAPs to approximately $22 per eligible employee for internal EAPs. A case study of seven EAPs, however, suggests that cost may vary widely depending on program characteristics and on the number of employees served. Intramarket competition among external EAPs, combined with the movement toward involving EAPs in managed care activities, has kept the costs of external EAPs relatively low over the past decade. Internal EAPs may have seen somewhat more of a rise in costs, but anecdotal evidence suggests that internal EAPs may be even more integrated in managed care and other workplace health promotion programs so that any rise in costs has been accompanied by an increase in services offered. Importantly, however, very little research has been done to estimate the cost *per service* of EAPs so that EAP services can be compared with other potential providers of comparable services.

Studies on the effectiveness and cost-effectiveness of EAPs suggest that they are effective in addressing employee problems and do so for relatively low cost, but this literature suffers from several shortcomings that preclude making definitive conclusions. Most notable are methodological problems, such as inadequate sample sizes and nonequivalent comparison samples. Perhaps as serious a limitation, however, is that many EAP effectiveness studies are conducted by EAPs themselves in an effort to demonstrate their value to company management.

Although more rigorous studies on EAP effectiveness are needed, the realities of workplace research often hamper efforts to design and conduct such studies. First and foremost is the changing role of EAPs. Because both the role of EAPs in the workplace and the services they offer have changed so dramatically over the past decade, EAPs represent a moving target that is very difficult to study. EAPs have moved from providing simple assessment and referral to providing short-term counseling, and then have moved back to assessment and referral but with a gatekeeper or case management role. Another factor limiting EAP research is the willingness of work sites to participate in an extended research study. Even if researchers obtain high-level cooperation, changes in workplace management can often result in workplaces' pulling out of studies before adequate data are collected.

In summary, EAPs represent an inexpensive gateway to mental health and substance abuse services. As the behavioral health care system in the United States has changed, so has the role of EAPs and the services they offer. These changes have often thwarted attempts to quantify the effectiveness of EAPs in helping with employee problems. Nonetheless, the continuing increase in the number of employers offering EAPs suggests that these employers view EAPs as a beneficial service for their employees.

ENCOPRESIS

Encopresis is generally regarded as a disorder of childhood. The term refers to repeated fecal soiling. The fourth edition

of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV;* American Psychiatric Association [ApA], 1994) gives four criteria for diagnosis of Encopresis: repeated passage of feces into inappropriate places; the occurrence of this behavior at least once a month for at least three months; a chronological age of the child of at least 4 years, or if there has been a developmental delay, a mental age of at least 4 years; and an inability to attribute the fecal incontinence to a general medical condition (except constipation) or to the effects of substances (e.g., a laxative).

The *DSM-IV* recognizes that fecal soiling may be voluntary or involuntary, but many family physicians and pediatricians would not diagnose voluntary fecal soiling as Encopresis, and would most often diagnose Encopresis as a consequence of constipation. The *DSM-IV* defines two subtypes of Encopresis. The first is with constipation and the inappropriate passage of feces due to overflow of fecal matter. About 80% of cases of Encopresis fall into this category, which may be called *Retentive Encopresis.* It is often the case that a child suffering from Retentive Encopresis has experienced pain or discomfort associated with bowel movements, leading to voluntary retention of stool. As large amounts of fecal material are retained, the rectum stretches to accommodate the increased mass. The larger the mass, the more painful the elimination, and the greater the motivation to hold the stool. Ultimately, the mass becomes large enough that the rectum is stretched to the point that the sensation of needing to have a bowel movement disappears. Indeed, the abdominal mass that results from this series of events is large enough to externally palpate in about half of the children with Encopresis (Loening-Baucke, 1994). The inappropriate soiling in Retentive Encopresis occurs as fecal matter leaks around the mass and escapes from the anus without the child's knowing that this has occurred.

The second form of Encopresis occurs without constipation and overflow incontinence (ApA, 1994) and accounts for about 20% of all cases of Encopresis (Kuhn, Marcus, & Pitner, 1999). It may be called *Nonretentive Encopresis.* Nonretentive Encopresis is usually associated with other behavioral problems, such as Oppositional Defiant Disorder or Conduct Disorder (ApA, 1994).

In addition to the distinction between Retentive and Nonretentive Encopresis, this disorder is further defined as being either primary or secondary. If a child has not been continent of stool for at least 1 year the disorder is referred to as *Primary Encopresis.* If a 1-year period of continence can be documented, the disorder is classified as *Secondary Encopresis.* Fifty to 60% of all children with Encopresis have Secondary Encopresis (Howe & Walker, 1992). Secondary Encopresis may be traced to a significant change in the life of the child, such as the birth of a sibling, a move to a new house, or beginning school.

The prevalence of Encopresis varies by age and by sex. Boys are three to four times more likely than girls to develop Encopresis, and, not surprisingly, the frequency decreases with age. Between the ages of 4 and 5 years about 3.5 to 4% of boys and 1 to 1.5% of girls are encopretic, whereas by age 8, the frequency is about 2.3% in boys and 0.7% in girls. By age 12 the frequency is 1.3% in boys and 0.3% in girls (Kaplan & Sadock, 1991). In rare cases, Encopresis may continue into adulthood.

In making the differential diagnosis of Encopresis it is important to distinguish the disorder from others caused by organic pathology. Hirschprung's disease, or aganglionic megacolon, is chief among the organic disorders that may be confused with functional Encopresis. Aganglionic megacolon is a congenital disorder in which the colon becomes dilated due to lack of neural supply. The patient may have an uncontrollable overflow of feces, but the rectum will often be empty. One of the symptoms of other medical disorders, including hypothyroidism, diabetes insipidus, and early inflammatory bowel disease also may mimic some aspects of Encopresis, but the other signs and symptoms associated with these conditions make differential diagnosis relatively easy.

Because Encopresis is probably caused by the interaction of a number of variables, including physiological predisposition, pain upon defecation, and difficulties in toilet training, treatment will often be multifaceted (Levine & Bakow, 1976). The family as well as the child should be involved in the treatment. Family counseling and therapy directed toward reducing conflict between the parents and child is advised. Family therapy sessions may also be useful in identifying precipitating factors within the child's psychosocial milieu and changing attitudes toward toilet training, if the problem is Primary Encopresis and the child has not been continent for an extended period of time.

In addition to family counseling therapy and a full developmental and behavioral analysis of the child, the treatment strategy should take into account the type of Encopresis. For example, treatment of Nonretentive Encopresis will primarily utilize behavioral therapies, with the use of laxatives only if the stool is not soft enough to produce comfortable bowel movements. Daily, scheduled, positive toilet sits should then be conducted and reinforcement given for successful defecation during these sits (Kuhn et al., 1999).

In treating cases of Retentive Encopresis medical treatment is employed on a regular basis. This treatment involves using enemas for disimpaction and laxatives to promote bowel movements. However, relying on medical intervention alone diminishes the success rate of treatment of Encopresis. Cox and colleagues (Cox, Sutphen, Borowitz, Kovatchev, & Ling, 1998) compared the effectiveness of (1) 3 months of treatment for Retentive Encopresis by medical treatment alone (enemas and laxatives); (2) medical treatment and enhanced toilet training employing reinforcement, scheduled toilet sits, and instruction and modeling to promote appropriate straining; or (3) medical treatment, toilet training, and biofeedback directed at relaxing the external anal sphincter during attempted defecation. They found that medical care alone reduced soilings per child by

21%, whereas enhanced toilet training and medical treatment caused a 76% reduction, and biofeedback and medical treatment yielded a 65% reduction. Additionally, Cox and colleagues reported that enhanced toilet training significantly benefitted more children than either of the other two treatment regimens and that fewer laxatives and fewer training sessions were necessary. The results of this study of 87 children are in general agreement with many other studies that behavioral therapy is a necessary addition to medical therapy in treating Retentive Encopresis.

EPIDEMIOLOGY OF MENTAL DISORDERS

Definition of Epidemiology

Epidemiology is the health science that studies patterns of occurrence of disease and disorder, as well as causal factors that influence such patterns in human or animal populations.

Prevalence and Incidence

Two principal types of rates are employed by epidemiologists: prevalence and incidence.

Prevalence

Prevalence rate has been likened to a snapshot insofar as it describes the health of a group within a specified time interval. This interval can either be an instance in time, most typically a day (point prevalence), or an interval of months, years, or even decades (period prevalence). The time interval need not be a point or period in calendar time but can refer to an event or events that happen to different individuals at different periods in calendar time. Within the designated time period, prevalence is defined as the number of individuals who are determined to have the disorder divided by the total number of individuals comprising the population of interest:

Prevalence rate =
Number of persons with the disorder during a specified time period/Total number of persons in the population during a specified time period

One frequently reported rate, lifetime prevalence, refers to a measure of the proportion of persons who have had the disorder at any time during their lives. Lifetime prevalence rates are nearly always based on retrospective reports and are susceptible to the inaccuracies characteristic of such reports.

Incidence

Incidence describes the rate of development of a disorder within a group over a designated period of time. This time period is factored into the formula defining incidence as follows:

Incidence rate =
Total number of new cases/Total number in the population at risk per time interval

In contrast to prevalence, which describes a proportion of *all* cases of the disorder in a designated population, incidence describes the continuing occurrence of *new* cases. Incidence is typically more difficult to determine than prevalence because persons who already have the disorder at the beginning of the study's time period must be identified and excluded from the incidence numerator. Because these individuals also are not at risk for developing the disease, they must also be excluded from the incidence denominator.

Risk Factors

It is possible to calculate the risk of developing a mental disorder on the basis of prevalence and incidence rates and a systematic account of other factors operating in the situation. Risk metrics indicate an associative or causal relationship between the presence of specific biological, environmental, or psychosocial factors and the occurrence of a disorder. *Relative risk* refers to the ratio of the incidence of a disorder among individuals known to have been exposed to a risk factor divided by the incidence among individuals

known not to have been exposed to that risk factor. *Attributable risk* is the absolute incidence of the disorder that can be attributed to exposure to the risk factor. Attributable risk is typically calculated by subtracting the incidence of the disorder among an exposed group from its total incidence among an unexposed group. It is a useful indication of what might result were the risk factor(s) to be removed.

Risks vary in the degree to which they are associated with disorders and in the degree to which they cause disorders. *Factor-related risks* are risks that are frequently, although not always, observed in conjunction with a disorder. *Factor-specific risks* are necessary, although not sufficient, prerequisites to developing a disorder. Patterns that suggest a causal connection between a risk factor and a mental disorder include consistent association, precedence, and specificity of effect. In consistent association, a clear relationship is reported between the risk factor and the mental disorder over repeated studies. Elimination of the risk factor eliminates or markedly ameliorates the disorder. Introduction of the risk factor precipitates or exacerbates the disorder. In precedence, the risk factor is observed to be present before the disorder is observed. In specificity of effect, the effect of the risk factor is specific to the disorder under investigation. A major goal of the epidemiology of mental disorders is the identification of risk factors that contribute to, precipitate, or maintain mental disorders.

Comparing rates of disorder between various groups is considerably important. Such comparisons are frequently expressed as differences between rates, as ratios of one rate to another, or of many rates to a standard rate.

Types of Studies

There are two fundamental types of epidemiological studies. *Descriptive studies* are undertaken to document the occurrence of disorders or disorder-related phenomena in a group. Descriptive studies generally measure the disorder and its related attributes in a somewhat diffuse or superficial manner. They provide observations concerning the relationship of disorders to such basic characteristics as age, gender, ethnic background, socioeconomic status, geographic location and distribution, time of occurrence, and so forth. *Analytic studies* are conducted to explain the observed pattern of the disorder within the group and thereby clarify the etiological factors involved in precipitating, maintaining, or alleviating the disorder. In contrast to descriptive studies, analytic studies tend to be more narrowly focused on a specific set of hypotheses and often require more rigorous study designs and more sophisticated quantitative analyses of findings. The three most basic types of analytic observational studies are prevalence studies, case-control studies, and cohort studies.

Prevalence studies investigate the relationship between disorders and other attributes of interest such as they exist in the population of interest during a particular time period. The presence, absence, or severity of the disorder is determined for each individual sampled, and the relationship between the attribute and the disease can be determined in either of two ways: (1) in terms of the presence, absence, or severity of the disorder in different population subgroups defined by the attribute, or (2) in terms of the presence, absence, or severity of symptoms for those determined to have the disorder versus those who were not.

Case-control studies are similar to prevalence studies in that they investigate the correlations between indicators of existing symptoms with other variables or attributes. The presence or absence of the disorder is determined for each member of the study and is systematically related to other factors or attributes. Typically, following an initial process of case determination, an appropriate control group of individuals without the disorder is identified. Correlations of other attributes to the disorder are determined by comparing the disordered group with controls for presence or severity of the attribute.

Cohort studies are undertaken to investigate more directly factors related to the development of the disorder. A group of individuals who are determined to be free of the disorder is identified at a particular time. Attributes of interest are measured in this cohort, then these individuals are followed up at various times to determine the development of the disorder(s) under study. The correlation of an attribute with the disorder is determined by splitting the population into subgroups according to the presence or level of the attribute initially and comparing the incidence of disorder among the various subgroups formed.

In actual practice, the neat distinction between descriptive and analytical studies is often blurred. A carefully designed and implemented descriptive study may provide a clear resolution of specific hypotheses. An analytic study focused on a specific hypothesis may coincidentally provide descriptive data of considerable interest.

Special Issues in the Epidemiology of Mental Disorders

The difficulties inherent in the diagnosis of mental disorders within modern American society are compounded when individuals from various minority groups or from non-Western cultural backgrounds are studied. Psychiatric epidemiologists have long appreciated that many mental disorders manifest as patterns of thought, affect, or behavior that deviate from dominant cultural beliefs and expectations and are found to be disturbing by those who think, feel, or act them out or to others around them. Because different cultures have established different standards and upheld different expectations for their members, it follows that what might be considered disturbing or disordered in one culture may fall comfortably within the normal range of experience for another culture. Some of the most influential studies in the history of mental health epidemiology have addressed these issues.

The Value of Epidemiology to the Mental Health Community

The value of properly conducted epidemiological studies for theory building and for the therapeutic practice of psychology is unquestionable. Valid epidemiological rates are of fundamental importance in alerting the mental health community to those types of individuals most likely to be afflicted with a particular disorder, where the disorder is most likely to occur geographically, and when it is most likely to manifest for the individual case or come to the attention of the professional mental health care community. Thus, valid epidemiological information helps guide the individual diagnostic process and also may aid in the selection of appropriate and effective intervention strategies. Reliable epidemiological information also is obviously valuable for efficient planning of community mental health services and facilities. By providing information regarding the etiology of mental disorders and by raising new hypotheses regarding the nature of their antecedents, course, and consequents, epidemiological data make fundamental contributions to theory building for both fundamental understanding and treatment of mental disorders.

ERIKSONIAN DEVELOPMENTAL STAGES

The developmental theory of Erik Erikson (1950, 1968) provides a life-span account of psychosocial development, which emphasizes the autonomous or conflict-free development of an adaptive ego that organizes experience. He postulates that human beings have a need to categorize and integrate their experiences, as well as a need to satisfy their basic biological needs. A consolidated sense of ego identity—a perceived sense of personal wholeness and "continuity of experience"—is considered to be necessary for optimal personal functioning.

The building and integrating of personality follows an eight-stage life-span sequence governed by what Erikson calls the *epigenetic principle,* which states that "anything that grows has a ground plan, and that out of this ground plan the parts arise, each part having its time of special ascendancy, until all parts have arisen to form a functioning whole" (Erikson 1968, p. 92). Each stage, from birth to old age, is marked by a normative crisis that must be confronted and negotiated. These bipolar crises are psychosocial in nature. Crisis resolutions have residual effects on the developing person, with each contributing to the totally formed personality. Ideally, resolutions should not be completely one-sided: A positively balanced ratio of the two poles indicates optimal progress.

The stages, which are assumed to be interdependent, build upon one another in a cumulative manner. Each stage contributes a unique personal quality of strength or virtue, such as hope or faith, to the evolving personality. The achievement of ego identity during adolescence is the central concept in this developmental scheme; it entails the synthesis and integration of prior experiences and developments and provides the foundation upon which future progress occurs.

Stage 1: Trust Versus Mistrust (Infancy)

At birth, infants are dominated by biological needs and drives. The reliability and quality of their relationship with caregivers will influence the extent to which they develop a sense of trust (or mistrust) in others, themselves, and the world in general. The virtue of *hope* is associated with this stage.

Stage 2: Autonomy Versus Doubt and Shame (Early Childhood)

Social demands for self-control and bodily regulation (toilet training) influence feelings of self-efficacy versus self-doubt. The quality of *will,* the willful self-discipline to do what is expected and expectable, emerges at stage two.

Stage 3: Initiative Versus Guilt (Preschool Age)

Here children begin actively exploring their environment. Will they sense guilt about these self-initiated activities, or will they feel justified in planning and asserting control over their activities? The virtue of *purpose*—the courage to pursue personally valued goals in spite of risks and possible failure—now ascends.

Stage 4: Industry Versus Inferiority (School Age)

The societal context in which the first three psychosocial conflicts are negotiated is predominantly the home and immediate family. In stage four, however, children begin formal instruction of some sort. Mastery of tasks and skills valued by one's teachers and the larger society becomes focal. The quality of *competence* is said to develop.

Stage 5: Identity and Diffusion (Adolescence)

This is the linchpin in Erikson's scheme, a time when adolescents actively attempt to synthesize their experiences in an effort to formulate a stable sense of identity. Although this process is psychosocial in nature—a social fit or "solidarity with group ideals" must occur—Erikson emphasizes reality testing and the acquisition of credible self-

knowledge. Youths come to view themselves as products of their previous experiences, and a unified sense of temporal self-continuity is experienced. Positive resolutions of prior crises—being trusting, autonomous, willful, and industrious—facilitate identity formation; previous failures may lead to identity diffusion. *Fidelity,* the ability to maintain commitments in spite of contradictory value systems, is the virtue that emerges during adolescence.

In Erikson's theory, development continues throughout life. The three adult stages, however, are directly affected by the identity achieved during adolescence.

Stage 6: Intimacy Versus Isolation (Young Adulthood)

In this stage, one must be able and willing to unite his or her identity with that of another. Since authentic disclosure and mutuality leave people vulnerable, a firm sense of identity is prerequisite. The quality that ascends during this stage is *love.*

Stage 7: Generativity Versus Stagnation (Middle Adulthood)

This is the time in the life span when one strives to actualize the identity that has been formed and shared with selected others. The generation or production of offspring, artifacts, ideas, products, and so forth is involved. The virtue of *care* emerges: Generative adults care for others through parenting, teaching, supervising, and so forth, whereas stagnating adults become self-absorbed in immediate personal needs and interests.

Stage 8: Integrity Versus Despair (Maturity)

The final stage focuses on the perceived completion or fulfillment of one's life cycle. *Wisdom* is the last virtue to emerge. Wise people understand the relativistic nature of knowledge and accept that their life had to be the way it was.

As a heuristic scheme, Erikson's theory has had a profound impact on contemporary psychology, especially adolescent development. Despite its popularity and apparent face validity, the empirical foundation for the stage theory is relatively weak. The imprecise nature of the theoretical constructs—for instance, hope or wisdom—as defined by Erikson has made it difficult for researchers to independently test specific predictions derived from the theory. Another obstacle has been the need for long-term longitudinal studies to evaluate Erikson's claims about the sequential nature of psychosocial stages and the processes responsible for life-span personality development. Nonetheless, productive lines of research based on and generally consistent with Erikson's views relevant to particular stages have emerged (see, for example, Berzonsky & Adams, 1999; Marcia, 1993; McAdams, Ruetzel, & Foley, 1986; Orlofsky, 1993).

ERRORS (TYPE I AND II)

Statistical tests, which attempt to infer whether or not variables are related in a population by evaluating data from smaller samples, are by no means foolproof. Occasionally sample information would seem to imply that, say, variable X is related to variable Y in the population, when in fact no such population relation exists. For example, a random sample of subjects receiving a treatment may get considerably higher scores on some outcome measure than a comparable random (control) group of subjects not receiving the treatment, although in fact the treatment is completely ineffective and these two samples only differ because higher-scoring subjects were randomly assigned to the treatment group. In this case, inferring that X (presence/absence of treatment) is related to Y (outcome measure) is an example of a *Type I error.* On the other hand, sample data may seem to imply that X and Y are unrelated when indeed they do have a relation in the population. For example, a treatment group may get very similar outcome scores to those from a control group, although in fact the treatment is effective and these two samples are similar only because fairly high-scoring subjects were randomly assigned to the control group. In this case, inferring that X (presence/absence of treatment) is unrelated to Y (score) is an example of a *Type II error.* These two types of errors are discussed briefly in this entry.

For the generic experimental example just described,

	Truth in population	
Inference	H_0 is true (X and Y unrelated)	H_0 is false (X and Y related)
X and Y sample relation not statistically significant; retain H_0 as tenable	accurate inference	inaccurate inference (Type II error)
X and Y sample relation statistically significant; reject H	inaccurate inference (Type I error)	accurate inference

Figure 1. Errors (type I and II).

two possible truths exist at the population level, and two possible conclusions may be derived from the sample information. For the populations, either the treatment has some average effect or it has none. This latter notion, that there is no average difference between scores from a population receiving a treatment and a control population, is termed the *null hypothesis* (symbolized H_0). Thus, a genuinely benign treatment means that H_0 is true, whereas a treatment that affects outcome *Y* means that H_0 is false. As for conclusions drawn from samples, if the two sample means (averages) are relatively similar (i.e., not differing statistically significantly) the guarded inference would be made that H_0 remains tenable. One need not actually believe that the treatment is completely ineffective in the population; one may merely feel that sufficient evidence has not been gathered to the contrary, thus retaining H_0 as a tenable explanation for the lack of statistical significance associated with the observed difference between the two sample means. Conversely, if the two sample means are statistically significantly different, then one would infer that H_0 is false and that the treatment has some effect (positive or negative, accordingly).

Crossing the two population and two sample conditions previously outlined defines four possible outcomes of a research endeavor, two representing accurate inference and two representing inaccurate inference (i.e., Type I and Type II errors). These are depicted in Figure 1. Consider first the cells on the left side of the figure, in which H_0 is true (i.e., treatment has no effect on outcome). The top left cell results when the observed sample relation between treatment (presence/absence) and outcome is not statistically significant; that is, the observed difference between sample means falls in the realm of what one would comfortably expect by chance if two population means truly do not differ. In this situation one would infer that H_0 remains tenable, and in fact the inference would be accurate because H_0 is true. In short, the study would have gathered no evidence that the treatment is effective, and in truth it has no effect in the population.

The bottom left cell, on the other hand, results when the observed sample relation between the variables of interest is statistically significant; that is, the observed difference between sample means falls outside the realm of what one would comfortably expect by chance when two population means truly do not differ. In this situation one would infer that H_0 should be rejected as false; however, the inference would be inaccurate because H_0 is true, and it is thus labeled a Type I error. Such an event would be an unfortunate random occurrence, in which two samples happened to be selected whose outcome measure scores were extremely disparate, but this disparity was merely a random occurrence and in no way reflective of any beneficial or detrimental treatment effect.

Now consider the right column of the figure, in which H_0 is false (i.e., treatment has some effect on outcome). The bottom right cell results when the observed sample relation between the variables of interest is statistically significant. In this situation one would infer that H_0 should be rejected as false, and in fact the inference would be accurate. Thus, the study would have gathered evidence that the treatment is related to test performance, and in truth such a relation does exist in the population.

The top right cell, on the other hand, results when the observed sample relation between treatment and outcome score is not statistically significant. In this situation one would infer that H_0 remains tenable; however, the inference would be inaccurate because H_0 is false, and it is thus labeled a Type II error. Such an event would be an unfortunate random occurrence, in which two samples happened to be selected whose outcome scores were not particularly disparate, but this lack of disparity was not reflective of the actual treatment effect.

In practice, researchers never know in which cell they fall because they never know if H_0 is true or false. Thus, the best strategy is to minimize the chance of making either error in inference. To reduce Type I errors, researchers often select an "alpha level" in which statistical significance will be proclaimed (and H_0 rejected) such that one seldom infers

a population relation where none truly exists. A common choice is the .05 level, thus deeming statistically significant a sample relation that is so unlikely as to be observed less than 5% of the time when no such relation exists in the population. To reduce Type II errors, and thereby increase the chance of inferring the existence of population relations when they truly exist (i.e., increase "statistical power"), researchers can use highly reliable outcome measures, use statistical techniques to reduce variability in *Y* unrelated to *X,* and use samples of adequate size. The reader is referred to any introductory social science statistics text for further discussion of these and related issues.

ESCAPE-AVOIDANCE LEARNING

Avoidance learning and extinction are typically studied in the rat with electric foot shock as the aversive stimulus. In active avoidance, the rat is often placed in a runway, the floor of which is electrified at one end and is, at least temporarily, safe at the other end. The rat must move to the opposite end to escape or avoid shock. Before shock is delivered, the subject has several seconds in which to respond. A naive subject, however, fails to avoid and is shocked on at least one trial before escaping the shock chamber. Thus traditional avoidance learning always includes escape behavior and is appropriately called *escape-avoidance learning.*

When the situation is arranged so that the subject cannot avoid but can only escape shock, the termination of shock is considered reinforcing (termed *negative reinforcement* by Skinnerians), and learning to escape is usually measured by a reduction in latency with successive shocks (trials). In a one-way situation (described later), a series of, say, 8 or 10 escape trials also can mediate perfect avoidance learning when the opportunity to avoid is provided.

With a two-way, or shuttlebox, situation avoidance learning is slow, escape responses prevail, and perfect performance is rarely, if ever, attained. In a shuttle situation, the subject must learn to shuttle from one end of the alley to the other every time a warning signal (buzzer or light) is presented. This is difficult to do because no section of the alley is uniquely associated with either shock or safety. Thus fear is conditioned to the whole apparatus, engendering freezing; the rat has no distinguishable place to go to relax or escape fear, and after each escape trial it must learn to avoid by running right back into the region where it just got shocked.

In a one-way box, however, the rat is placed in a start chamber specifically associated with shock to which fear is conditioned, and the rat avoids by approaching a particular chamber that is consistently safe (i.e., where fear is clearly reduced or relaxation can occur). Some subjects in a one-way box learn to avoid in one trial, and learning to a 100% level in a mean of three or four trials is not unusual. Here the use of distinctive chambers and increasing the shock level up to a point facilitates learning. Presumably fear and safety are thereby segregated better, and reinforcement is enhanced (greater fear reduction), whereas the opposite is true in a shuttlebox, where conditioned fear (competition from freezing and the like) is enhanced by these manipulations. The same manipulations that facilitate or hinder avoidance learning have been shown to have parallel effects in pure escape learning by Franchina and associates.

In passive avoidance, the subject avoids shock by not making a particular response. For example, the rat is placed on a small platform surrounded by an electrified grid. If it remains on the platform without stepping down, the rat avoids passively. Because it yields fast learning and is simple to use, many studies of amnesia and other behavioral effects of biological intervention use the passive technique for assessment purposes. Basically, the use of punishment, in which an aversive stimulus is contingent on a particular response, is the same as passive avoidance. Passive avoidance is impeded if an alternative safe place to approach actively is available after the rat has been shocked for stepping down, and the more so the longer the rat remains in this safe place.

Mowrer's two-factor theory, or fear hypothesis, provides the main explanation of avoidance learning. Fear is conditioned to the shock area or warning signal, and escape from fear or the reduction of fear when the shock area or warning signal is removed is the reinforcement for the avoidance response (this is called *secondary negative reinforcement* by Skinnerians, and the concept of fear is not invoked). Research by Denny and associates indicates that 2.5 min away from shock or fear-provoking stimuli on each trial provides a good opportunity to relax, confers optimal approach value to the nonshock or safe area, and yields optimal avoidance learning in one-way situations. Also, the concept of relaxation in this context is especially valuable for explaining the extinction of fear-related behaviors such as escape and avoidance. Relaxation is directly incompatible with fear and presumably constitutes the competing response that extinguishes fear. In one-way situations, extinction appears to originate in the safe area, where the longer the subject is confined, the more it relaxes, and the faster fear extinguishes, especially if the safe area is similar to the shock region.

Tortora, working with vicious dogs that had presumably learned to avoid punishment by being aggressive, trained them to avoid shock by promptly following 15 different commands (e.g., down, here, and heel). For many dogs a tone (safety signal) followed each correct response and was associated with a long shock-free, relaxation period. The safety tone clearly facilitated training, producing manageable, prosocial animals.

Results from a number of recent escape-avoidance studies indicate that without fear there is no tendency to avoid or to approach safety.

ETHICAL TREATMENT OF ANIMALS

In the quarter century since the publication of Peter Singer's *Animal Liberation* (1975) reopened discussion of our use of animals other than humans (hereafter, animals) in scientific research, three major developments have occurred.

First, within moral philosophy, several theories have been expounded regarding the ethics of this use. In addition to Singer's utilitarian ethic, Regan's (1983) eponymous rights theory ("animal rights movement") and, more recently, feminist, communitarian, and contractarian theories, together have assured a secure place for this topic in courses on moral philosophy.

The theories all attempt to answer the question of the moral considerability of animals and to infer the policy and practices that follow from the standing claimed for them. For example, beyond that moral consideration due a sentient being, Wise (2000) argues that some animals (e.g., chimpanzees) are persons and this status obligates us to give them legal as well as ethical standing.

Second, in the area of institutional self-regulation and governmental regulation, following the passage of federal legislation in 1966 and subsequent amendments, review committees now oversee almost all laboratories engaged in animal research. Although this mechanism is modeled after the successful institutional review boards for research involving human subjects, its adequacy is hotly debated. Do the preponderance of animal researchers on these review boards and the exclusion of rodents and birds (the most frequent objects of study in psychological animal research) from the committees' purview undermine effectiveness and credibility? Or, does the exercise of requirements such as the search for alternatives that replace animals, or at least reduce their numbers and extent of suffering, and the provision that both husbandry and procedures ensure the well-being of primates constitute adequate policing and reforming practices?

Animal Studies

Symbolized by Singer's acceptance of the position of Decamp Professor of Bioethics at Princeton University, the third development in the discussion of animals' use in research is the emergence of a field of Animal Studies, which provides academic foundation to a progressive social movement. Scholars in the social and natural sciences as well as the humanities apply the methods of their respective disciplines to the study of nonhuman animals and human-animal interfaces. Books published by major publishing houses, book series, journals (e.g., *Society and Animals* and *Anthrozoos*), and university programs, courses, and chairs devoted to animal studies constitute a robust intellectual infrastructure. The defining feature of Animal Studies is the shift from the study of nonhuman animals as representative objects, models, cultural artifacts, and symbols of human phenomena to subjects in the full sense of that term.

Psychology's Ambivalence

The role of psychology in these three developments has been mixed. Plous (1996) found a high level of support for research involving observation and even confinement. However, when asked about research involving pain or death to primates and rats, many psychologists (62.1% and 44.4%, respectively, for the two animal groups) indicate that such research is unjustified even when the research is described as "institutionally approved and deemed of scientific merit" (p. 1171).

On the negative side of psychology's role, several writers, including Singer, single out psychological research for criticism beyond its proportionate share of the research enterprise. Psychology also contributed a cause célèbre of abuse (the Silver Spring monkeys) as a psychology laboratory had its major federal support grant suspended. Regarding the field's general response to the issue of psychological animal research, two psychologists chided the field for adopting a "strategic defensive posture" (Gluck & Kubacki, 1991, p. 158).

More positively, two British psychologists contributed conceptual advances in the debate: Ryder coined the term *speciesism,* while Heim articulated the notion that there are ethical limits on our use of animals that are independent of any beneficial ends. A number of psychologists have conducted noninvasive animal research with primates and other animals that demonstrates the sophisticated capabilities of these animals, such as communication, self-reflection, and attribution of mind. The findings have raised the ethical bar to the use of animals in invasive research.

Psychologists also have contributed to the critique of animal research by adding science-based evidence and argument to the debate within ethics (e.g., Shapiro, 1998). They also have developed scales to measure degree of pain and harm, and provided empirical studies demonstrating the link between violence toward humans and other animals.

Increasingly, clinical psychologists are capitalizing on the empirically demonstrated social support, interpersonal facilitation, and other beneficial and therapeutic effects of involvement in a compassionate and respectful human-

animal relation. Therapists use animals as adjuncts in individual therapy (animal-assisted therapy). Residential group settings also use caring for animals as a vehicle for developing mutual, responsible relationships. A number of psychologists have chosen careers working in organizations in which the mission is the abolition or reform of invasive animal research, and one group of psychologists (Psychologists for the Ethical Treatment of Animals) has organized as animal advocates. In response to legislation in 18 states allowing the judge to require counseling for convicted animal abusers, Jory and Randour (1999) have developed a treatment manual for this population. Through these and other avenues, psychology is moving from a defensive to a constructive and progressive position on the issue of the ethical treatment of animals.

ETHNOCENTRISM

The term *ethnic* has been in use in the written English language at least since the fifteenth century and was derived from *ethnos* in Greek, which was interpreted variously as people, race, culture, or nation. The term was also used by the Greeks to denote heathens, as the term *ethnos* itself was derived from *ethnikos.* The term *ethnocentric* was used in the literature as early as 1898, though the term *ethnicity* is supposed to have been introduced in the 1940s (Sollors, 1996). The concept of ethnocentrism was defined by Sumner in 1906 as "this view of things in which one's own group is the center of everything, and all others are scaled and rated with reference to it. . . . Each group nourishes its own pride and vanity, boasts itself superior, exalts its own divinities, and looks with contempt on outsiders" (Sumner, 1959). The Greeks and Romans, for example, considered all outsiders barbarians. Sumner's use of the term *ethnocentrism* has also been interpreted more broadly as an ethnocentric syndrome (Le Vine & Campbell, 1972). Ethnocentrism is not limited to racial or geographic factors alone; it is based on many other social, cultural, and linguistic factors. It can even be based on ideologies. The boundaries between different ethnic groups are not always clearly demarcated, as ethnicity is often subjective in nature. There are different levels of ethnocentricity, and the extent of ethnocentrism varies considerably (Brewer & Campbell, 1976). The concept of social distance introduced in the 1920s enabled researchers to measure the extent of perceived distance among different ethnic groups. Although the concept of ethnocentrism was originally used as a group-based concept, it is now used to measure individual views and perspectives as well. Concepts such as "the stranger" and "marginal man" introduced by Simmel convey the idea of an individual who generally provided a bridge between the in-group and out-groups. The authoritarian personality studies have addressed the problem of relationship between ethnocentrism and discernible personality traits and characteristics (Forbes, 1985). Attitude scales such as the F scale provide other examples of an authoritarian personality measurement (Brewer & Campbell, 1976). Ethnocentrism, however, needs to be clearly distinguished from xenophobia, jingoism, and chauvinism, although they are all based on ethnocentric views.

Causes, Consequences, and Reduction of Ethnocentrism

The causes and manifestation of ethnocentrism can take different forms. One type of explanation would be based on personality factors of individuals. Another form of ethnocentric behavior is contextual or situational, such as the loss of jobs due to competition from a neighboring state or groups. One group or nation can be transformed from a friend to an enemy and vice versa after the end of a war. The reasons for another type of ethnocentrism may vary from mistrust of the stranger to the aims of conquest and subjugation of another group for various reasons.

The more serious negative aspects of ethnocentrism have often been manifested throughout history as violent conflicts, wars, slavery, ethnic cleansing, and genocide. The protohistorical accounts of warfare were based on tribal affiliations. The crusades in the Middle Ages, conflict in Northern Ireland, and the Nazi holocaust were based on religion. In addition to tribal and religious basis of ethnocentrism, race, colonialism, and ethnonationalism have contributed toward distinctly negative and sometimes savage consequences. Prejudicial attitudes and discriminatory behavior of Whites and African Americans in the United States are examples of ethnocentrism based on racial lines.

The apartheid practices in South Africa constituted an example of colonial ethnocentrism and concomitant racism that was common in most colonial situations. Even in multiracial or multicultural colonies, the primary White and non-White grouping, along with the dichotomy of the master and the subjugated, persisted because of the convergence of power, color, race, language, and class differences. The colonial perspective was often Eurocentric, with hierarchical and discriminatory lines drawn between the European colonizer and the colonized. The perceived distinctions of superiority and inferiority of groups became a self-fulfilling prophecy. Race relations in the United States have often been described as internal colonialism by Marxists and non-Marxists alike. The minority ethnic groups are often disrespectful of their own ethnicity in contrast with the ethnic group that is in power, a phenomenon often noticed in the colonial context. Ethnonationalism has manifested in the creation of more new nations in the last century than any other century in history. Many of these nations were created as a result of violent conflicts, atrocities, and civil wars.

Ethnocentrism has also been utilized as a means to bolster the in-group feelings and group solidarity built along ethnic lines. Terms of reference such as “brother,” “sister,” or “white man’s burden” and the development of ethnic literature, clubs, and distinct modes of dressing are examples of activities intended to maintain the separate identity and self-respect of minorities. Socialization through the family, schools, media, peer groups, and religious teachings is a major avenue of germination and indoctrination of ethnocentrism. However, it must be strongly emphasized that all ethnic relations are not necessarily violent. There are many long-standing examples of peaceful coexistence of different ethnic groups in spite of their ethnocentric beliefs.

Ethnocentrism is a learned behavior, rooted in differences covering a variety of characteristics, and thus can be unlearned. Cultural contact has been tried as one of the approaches to reduce ethnocentrism, with the Olympic games being one example. Another solution that has been suggested is the submerging of local ethnic groups into a larger collective such as a nationality. This was the assumption made in the case of countries with intertribal or intergroup conflicts or rivalries, such as Nigeria. It was often wrongly believed that these conflicts would be subordinated or submerged in the superordinate collective such as that of nationhood. Education and socialization of children in schools through the emphasis on multicultural perspectives is another technique used to reduce ethnocentric biases. Legal measures have sometimes been effective in reducing discriminatory behavior in a few cases, but they are not likely to make an impact in case of long-standing distrust or animosities among different groups. Social changes may reduce or enhance ethnocentrism between two groups. Cross-cutting loyalties, such as different religious affiliations but a common language, would oftentimes result in lowered levels of ethnocentrism. However, regardless of many efforts, different and new types of ethnocentric conflicts keep cropping up in many places all around the world, as it recently did in the form of terrorism. The inherent differences in the worldviews, cultural values, and belief systems are always vying for legitimization. In spite of the importance of the subject of ethnocentrism, the research on this topic is surprisingly sparse so far.

ETHNOCULTURAL PSYCHOTHERAPY

Ethnocultural psychotherapy integrates ethnicity and culture into assessment and treatment. Complementing targeted mental health interventions with historical and current cultural practices, ethnocultural psychotherapy employs multigenerational genograms, transitional maps, fables, testimonies, and other indigenous psychological techniques to acknowledge the concept of self as an internal ethnocultural representation.

Ethnocultural psychotherapy pays particular attention to issues prevalent among culturally diverse individuals, including translocation and adaptation, inclusion and exclusion, power and powerlessness, and identity transformation. One of the tools of this therapy, the ethnocultural assessment, explores the developmental stages that contribute to the ethnocultural identity. Used in both diagnosis and treatment, the ethnocultural assessment examines heritage, myth, niche, adjustment, and relationships.

The genetic, biological, and sociocultural familial heritage provides a backdrop for exploration of the family myth: the circumstances that led to the client’s (and multigenerational family’s) cultural transitions. The niche—derived from a posttransition analysis—is based on the client’s intellectual and emotional perception of his or her family’s ethnocultural identity in the host society since the translocation. The adjustment stage refers to the client’s own perceived adaptation in the host culture as an indi-

vidual distinct from the rest of the family. This involves a therapeutic exploration of the contrasts between the client's ethnocultural identity and that of his or her work and social milieus. Finally, the relationships stage examines transference and countertransference, considering the therapist's own ethnocultural assessment to determine specific areas of similarity and difference. Besides obtaining a wealth of information crucial for therapeutic intervention, performance of the assessment often opens new channels of recognition of the self in the other.

Ethnocultural psychotherapy facilitates a cultural analysis, which aims at critical consciousness, or the process of transformation that oppressed individuals experience while educating themselves in a dialectic conversation with their world. Through this process clients learn to read their condition as well as authoring their own reality. The therapeutic relationship functions as the dialogue that helps clients to express their truth, assert their identity, heal, and achieve autonomy.

ETHOLOGY

Ethology is defined as the study of animal behavior in its natural environment, including its physical, biological, and social aspects. Ethology is also concerned with the role of Darwinian natural selection in shaping animal behavior. This implies that the behavior is related to genotypes that are in turn a product of the species's evolutionary history. Furthermore, gene selection is assumed to have been influenced by the consequences of naturally occurring behaviors. Jaynes (1969) has written a comprehensive review of ethology's origins.

Concepts in Classic Ethology

The starting point for ethological study has been *ethograms,* which are extensive, highly detailed descriptions of a species's behaviors in its natural environment. They originated in the work of European naturalists such as O. Heinroth, J. H. Fabre, and D. Spaulding during the late nineteenth and early twentieth centuries. These early ethologists were impressed by the constant, stereotyped nature of many adaptive behaviors that were often labeled as innate or instinctive.

Fixed-action patterns are specific, stereotyped behaviors characteristic of a species. Fixed-action patterns are so constant that they have been used as criteria for taxonomic classification of species (Hinde, 1970). Furthermore, fixed-action patterns are usually elicited by specific stimuli (called *releasers* or *sign stimuli*). Occasionally, an artificial stimulus termed a *supranormal stimulus* is more effective than the naturally occurring one in releasing a fixed-action pattern.

The ethological deprivation experiment is a type of restriction that differs from the typical deprivation experiment in American experimental psychology. In the ethological deprivation experiment only a small, carefully chosen set of stimuli are withheld from the subjects in order to prevent practice of a target behavior. The ethologist makes a point of imposing no more deprivation than necessary to prevent the occurrence of the target behavior. If, following the deprivation, the animal shows the full fixed-action pattern in response to the appropriate releasing stimulus, then the behavior did not depend on previous practice. Early ethologists further concluded that the behavior was innate and did not depend on any prior learning, an inference that is not necessarily justified.

Later Developments in Ethology

Following Lorenz and Tinbergen's establishment of a basic theoretical foundation for ethology in the 1930s, several major changes occurred in the theoretical and empirical approaches of ethologists to animal behavior. A major change in classic ethological theory has been an increasing awareness of the strong influence of learning in animal behavior, including many fixed-action patterns. The best-known example is imprinting, which was initially regarded by Lorenz as an innately released following behavior in recently born or hatched animals of some species. Later research showed that a simple and rapid conditioning probably underlies imprinting (Moltz, 1963).

The sophistication of ethological research has increased dramatically during the past 40 years. One facet of modern ethological research is a focus on quantification of the adaptive value of behavior. The study of territoriality in golden-winged sunbirds (Gill & Wolf, 1975) was an early example that showed how territorial defense could be predicted by analysis of calories expended in foraging or defending territories and caloric values of food sources in alternative territories. Optimality theory assumes that natural selection has adjusted animal behavior, such as foraging for food in the natural habitat, so as to achieve an optimum balance between costs and benefits (Krebs & Davis, 1993). Feeding, predator-prey relationships, and population regulation have been frequent issues addressed by behavioral ecologists.

The field of behavioral ecology has also emerged from classic ethology. Behavioral ecology is focused on the interactions of animals within their entire ecological communities, including the inorganic environment, plants, other animal species, and their own species (Krebs & Davis, 1993).

One of the most dramatic findings to emerge from recent ethological research is the increasingly abundant evidence of evolved behavioral dispositions that promote group cohesion and reduce aggression (de Waal, 1996). These processes include reconciliation, reciprocity of both positive and negative acts, and consolation, as well as processes having some resemblance to sympathy and altruism. The power of these prosocial processes was shown by the observation that when the population density of rhesus monkeys was increased by a factor of 646, there was no increase in aggression but marked increases in appeasement and submissive gestures (de Waal, 1996).

Ethological studies in recent years have also overlapped with the domain of sociobiology, wherein a large variety of behaviors are explained in terms of an expanded definition of evolutionary fitness that includes natural selection for benefits that accrue to all genetic relatives (kin selection: Trivers, 1985).

Elements of game theory have been introduced in ethology based on evidence that the old idea that a single set of species-specific behaviors characterizes all species is incorrect. In fact, behavioral polymorphism (distinctly different types of behaviors in different animals within the same species) has been identified in several species. These polymorphisms may be determined by an animal's social and environmental circumstances or may be genetically determined. Behaviors displaying polymorphic variation are often different reproductive strategies, with each having the same evolutionary fitness.

EVERYDAY COGNITION

Everyday cognition refers to the study of thinking—memory, reasoning, and judgment—in naturalistic settings and with real-world content. Examples of such thinking include the way in which we form impressions of people in our everyday lives, how we retrieve memories from our childhood, how we decide which brand is the best buy at the supermarket, and how we judge the likelihood of landing a job that we've applied for. The study of everyday cognition can be contrasted with traditional laboratory research on memory and thinking, where cognitive processes are studied outside of their everyday context and are assumed to be completely general (even universal) across contexts and materials. Thus, for example, rather than studying general problem-solving processes in the lab, researchers in everyday cognition have examined how grocery shoppers use nonstandard math in making their buying decisions and how dairy workers fill orders and determine the price of these orders. Similarly, rather than looking at the degree to which lab participants reason with abstract probability problems or simulations of lotteries or gambles, researchers in naturalistic decision making have looked at the real-world decision making of urban firefighters and military commanders in the field.

Everyday cognition research is also notable for the wide variety of methods used, in contrast to traditional laboratory research. Thus, for example, these methods include diary keeping, survey research, field studies, analyzing think-aloud protocols, and the use of archival data, to name just a few (in addition to traditional laboratory techniques). Everyday cognition research also often involves a focus on special populations (e.g., amnesia patients, experts in everyday skills such as typewriting or baseball) and applied problems (e.g., eyewitness testimony, adherence to schedules of medication).

Two prototypical topics in the area of everyday cognition that illustrate some of these differences from traditional laboratory research on memory and cognition, as well as the variety of different techniques used in the former area, are *autobiographical memory* and the study of *practical reasoning* in work settings. The topic of autobiographical memory (AM) is concerned with what we recall about our personal life history: how accurate or distorted these memories are, how they are distributed over the different periods of our lives (e.g., early childhood, adolescence, middle

age), how events are represented and organized in memory, and how such memories are retrieved. In general, studies of AM differ from traditional laboratory studies of memory in that researchers on AM typically have little control over the conditions under which such memories are acquired and rehearsed and, in many cases, no way of judging their accuracy. In addition, AMs are typically months, years, or even decades old rather than being acquired in the same research session, and, unlike the memories studied in most lab research, AMs typically have significant personal meaning for the participant.

Studies on AM have used a variety of different research methods. For example, much traditional research has used a cue word method in which participants are asked to retrieve personal memories that match a given cue (e.g., an emotion or an object). In one particular version of this sort of study, participants were asked to recall AMs that met certain criteria, such as a memory of a time when they drove on the freeway and nearly had an accident. By presenting cues in different orders and measuring the time it took for participants to retrieve a memory, this research concluded that AMs are represented primarily in terms of activities (e.g., going to a restaurant) rather than in terms of general actions that are associated with a variety of contexts and activities (e.g., paying the bill), emotions, people, or the like.

In addition to studies using this sort of more familiar experimental manipulation, research on AM has also used long-term diary studies with single or small numbers of participants. For example, in two classic studies individual researchers recorded samples of events and experiences over 6-year periods of their lives, along with ratings of these events (e.g., in terms of salience and emotionality) and, in one case, details of the who, what, when, and where of the event. These researchers then tested their memory for randomly sampled examples of these events, either on a monthly basis or in the final year of the 6-year period. A common finding of both of these studies is that the diarists' memory for events proved to be much better than would be expected from traditional lab studies of memory. A subsequent study in which the recorded events were randomly sampled (i.e., by having participants write a description of whatever they were doing and thinking when a beeper they were carrying went off) found somewhat greater forgetting, though still better recall than that found in most lab studies of memory. Finally, some recent diary studies have focused on the involuntary, automatic recall of AMs, such as memories elicited by some odor or song or scene, as opposed to deliberate, strategic memory searches.

A second example of everyday cognition research can be found in a set of studies by Sylvia Scribner on the practical problem solving engaged in by workers at a dairy plant. This research looked at product assembly workers who had to fill orders by retrieving cases and partial cases of dairy products from a large ice box, drivers who had to calculate the price for specific quantities of milk and other dairy products, and inventory workers who took stock of existing supplies in the ice box. This research is of interest for a couple of different reasons. First, Scribner began with ethnographic observations of these workers performing their everyday tasks in a "natural" setting (i.e., the dairy) rather than trying to abstract some general processes out of that setting. From these observations Scribner formulated a conception of the workers' practical problem-solving strategies, which she then tested by means of task simulations with these same workers, as well as by comparing the experienced workers' performance with that of relative novices on the same tasks. Based on this evidence, Scribner concluded that the dairy workers typically reformulated the problem facing them in such a way that they could perform the task with optimal efficiency and flexibility and with minimal effort, for example, by completing an order by moving the minimal number of units. These workers also used properties of the environment (e.g., known dimensions of the ice box) in problem solving.

In general, Scribner, like so many other researchers in everyday cognition, has been at pains to point out how this sort of practical reasoning differs from the sorts of problem-solving tasks studied in traditional laboratory research. Thus, for example, practical, everyday problems typically relate to the overall goals and activities of the problem solver, rather than simply being isolated tasks to be solved for their own sake. Similarly, the workers' use of the environment in their problem solutions differs from the usual emphasis in laboratory studies (or school settings) on participants (or students) solving problems symbolically or "in the head."

Research on everyday cognition clearly takes a variety of different forms and, at this point in time, is still a work in progress. Nevertheless, the study of cognitive processes in real-world settings and with everyday materials presently offers a significant challenge to traditional research on memory and cognition.

California State University

EVOLUTIONARY PSYCHOLOGY

Human psychology is a product of the human nervous system. Neural mechanisms, often clustered in the brain, gather and process information from the environment, interact, and execute all actions. Every conscious and unconscious mental phenomenon—motivations, emotions, plans, and so on—derives from neural activity. Even the most mundane behaviors require precise unconscious calculations. Walking, for instance, requires extensive feedback

and sensory integration in order to coordinate intricate muscle movement.

The only known process resulting in complex biological systems, such as the human nervous system, is evolution by natural selection. Natural selection is the process whereby genetically heritable traits within a population that directly or indirectly increase the bearer's reproduction pass more frequently into the next generation than less beneficial genetically heritable traits. Environmental features (food, conspecifics, substrate, etc.) that affect reproduction determine the direction of natural selection. Because human psychology is a product of the nervous system, and because evolution by natural selection is the only known mechanism that creates complex biological systems, all human psychology is a product of evolution by natural selection.

Natural selection produces adaptations: genetically heritable traits that serve context-specific purposes. Some adaptations perform functions that are helpful in modern contexts—reflexively pulling one's hand away from sudden intense heat before recognizing pain still minimizes tissue damage. Some adaptations, however, no longer function well in modern human environments. Our taste preference for fats now leads to obesity and increases our chance of suffering from cardiovascular disease and diabetes. It is difficult to understand adaptations, such as a preference for fats, without understanding their functions.

The fundamental function of every adaptation is to facilitate the reproduction of its host, ultimately to propagate the gene or genes that code for that adaptation. Adaptations exist over time because they propagated more numerously than other traits or forms of the same trait in a certain environment and withstood some measure of natural selection. Because natural selection eliminates traits that inferiorly propagate themselves compared to other traits (adaptations), the tautological function of an adaptation is to facilitate reproductive success in the environment in which it evolved. Adaptations such as the human nervous system, and thus all psychological mechanisms, are ultimately designed to propagate the genes for which they code.

Reproductive success can be subtle: An adaptation that grants a 1% reproductive advantage over other adaptations (or other forms of the same adaptation) can come to dominate a population after many generations. Reproductive success is context specific; that which is successful in one environment is often unsuccessful in different environments. Human reproductive success is often specifically difficult to understand due to the gap between the environment in which our psychology evolved and our modern environment.

Some aspects of modern human environments remain very similar to the environments in which human psychological mechanisms evolved, such as pair bonding in short- and long-term relationships, language use, and kinship networks. However, significant features of our current environment differ greatly from that of our ancestors. Among other environmental features, our ancestors did not benefit from the use of electricity, safe and easily acquired food, and indoor plumbing. Consequently, we possess no psychological adaptations designed to handle the problems associated with these new environmental features. Evolutionary psychology considers how human ancestral environments might be responsible for seemingly irrational modern human cognition and behavior. Many features of human psychology do not make adaptive sense because human behavior evolved in a sometimes drastically different environment.

Human taste preference for fatty foods illustrates the discrepancy between the environment in which human psychology evolved and modern environments. It is illogical in modern times to possess strong fat taste preferences because fat is easily accessible and high fat intake often leads to various diseases. Evolved fat preference makes adaptive sense only when we consider the famine conditions recurrent over human evolutionary history and the great difficulty ancestral humans would have faced in securing fatty foods. Ancestral humans that preferred fat (which is calorically dense) were more likely to survive and reproduce than those who did not prefer fats when food became intermittently available. The added caloric benefit of heritable fat preference outweighed fat's deleterious effects because fat was not widely available and thus not consumed in the manner and amounts that now induce health problems. The fat preference that was beneficial for our ancestors is now often harmful due to differences between modern environments and the environment in which this element of human psychology evolved.

Relatively rapid and inconsistent environmental change typifies the last 10,000 years of human existence, yet new adaptations regularly take 1,000 to 10,000 generations (15,000 to 150,000 human years) to spread throughout a population. Genes for adaptations specific to modern environments have not had sufficient time to propagate, even if such adaptations could exist. As William Allman suggests, our modern skulls house a "Stone Age mind" (Allman, 1994).

The indelible marks of evolution by natural selection pervade human psychology. However, the complexities of evolutionary theory and human behavior delayed a synthesis of the two fields until the latter part of the twentieth century. Because human behavioral scientists have not yet largely utilized evolutionary principles, many productive advances await evolutionarily informed researchers. Evolution provides insight into the design and purpose of behavior across realms of behavioral science, be it clinical psychology, neuroscience, linguistics, or otherwise. Perhaps we may one day achieve that which Darwin predicted in *The Origin of Species* (1859): "In the distant future I see open fields for far more important researches. Psychology will be based on a new foundation."

EXCITATORY AND INHIBITORY SYNAPSES

Chemical synapses—that is, synapses that use a chemical neurotransmitter to transfer information from one neuron to another—can be excitatory or inhibitory, depending on their effect on the postsynaptic neuron. Synapses releasing a neurotransmitter that brings the membrane potential of the postsynaptic neuron toward the threshold for generating action potentials are said to be excitatory. Alternatively, inhibitory synapses drive the membrane potential of the postsynaptic neuron away from the threshold for generating action potentials. The effect of a synapse is determined by its neurotransmitter content and the properties of the receptors present on the postsynaptic membrane. For example, in the adult mammalian brain, glutamate synapses are known to be excitatory, whereas gamma-aminobutyric acid (GABA) synapses are inhibitory. Meanwhile, synapses containing acetylcholine can be either excitatory or inhibitory, depending on the type of receptors present at a given synapse. Thus, at the neuromuscular junction, acetylcholine produces synaptic excitation by acting on a nicotinic receptor, while in the heart it acts on the inhibitory muscarinic receptor, resulting in slowing of the heart rate. Moreover, acetylcholine can have both excitatory and inhibitory effects in the same region, as described in the hippocampus (Ben-Ari, Krnjević, Reinhardt, & Ropert, 1981; Dodd, Dingledine, & Kelly, 1981). Even more complex is the case of neurons releasing two neurotransmitters with opposing action, for example, glutamate and GABA in hippocampal granule cells (Walker, Ruiz, & Kullmann, 2001), and dopamine and glutamate in ventral midbrain neurons (Sulzer et al., 1998). Postsynaptic factors may be involved in regulating the differential release of such cotransmitters, as demonstrated in sympathetic neurons, producing both norepinephrine (excitatory) and acetylcholine (inhibitory). In these neurons, brain-derived neurotrophic factor (BDNF) favors the secretion of acetylcholine, and its presence can thus transform an excitatory synapse into an inhibitory one within minutes (Yang, Slonimsky, & Birren, 2002).

In many instances, excitatory and inhibitory synapses appear to differ morphologically. In the cerebral cortex, Gray (1959) described two morphological types of synapses, type 1 and type 2, which were later correlated to excitatory and inhibitory synapses (Eccles, 1964). Type 1 synapses have a prominent postsynaptic density and a synaptic cleft about 20 nm wide. They are also called *asymmetric synapses,* because the postsynaptic membrane specialization is thicker than the presynaptic one (Colonnier, 1968). Most type 1 or asymmetric synapses contain round synaptic vesicles, so they are also termed S-type (S for spheroid vesicles). The great majority of type 1 synapses in the cerebral cortex use glutamate as a neurotransmitter, and they are excitatory. Type 2 synapses are characterized by a less pronounced postsynaptic density and a narrower synaptic cleft of about 12 nm. They are also known as *symmetric,* because the pre- and postsynaptic membrane specializations have a similar appearance. These synapses contain both round and flat synaptic vesicles after aldehyde fixation, hence the term F-type (F for flat vesicles). In the cerebral cortex, the vast majority of type 2 or symmetric synapses contain GABA as a neurotransmitter and are inhibitory. Glycine, another major inhibitory neurotransmitter of the brain, is also found in symmetric synapses in the spinal cord, cochlear nucleus, and other regions of the brain (reviewed in Legendre, 2001).

Although this correlation between morphology and function essentially holds true for the synapses in the adult cerebral cortex, this is not always the case during development or in other regions of the brain. For example, in the very young cerebral cortex, GABA cannot be detected by immunocytochemistry in as many as three quarters of the symmetric synapses (Micheva & Beaulieu, 1996). In some regions of the brain, such as the spinal cord, basal ganglia, and inferior olive, GABA terminals have been observed to also form asymmetric synapses. Thus, although the correlation between the two morphological types of synapses and their function holds true in a significant number of cases, it has to be used with caution, and always in conjunction with an immunocytochemical identification of the neurotransmitter type.

The excitatory and inhibitory synapses have been the object of many studies in different regions of the brain. For example, in the cerebral cortex, it was found that these two types of synapses differ in both their quantity and their distribution. The excitatory synapses represent the majority of synapses (more than 80%) and contact predominantly distal parts of the neuron, such as dendritic spines (i.e., the protoplasmic protrusions extending from the dendrites of some cells). Inhibitory synapses, meanwhile, are much less numerous and are most often found on proximal parts of the neuron such as dendritic shafts and cell bodies (e.g., Beaulieu, Kisvárday, Somogyi, Cynader, & Cowey, 1992). These morphological data appear to contradict physiological studies that indicate the existence of a balance between the excitatory and inhibitory neurotransmission in the cortex. However, even though the excitatory connections are much more abundant, the cortical inhibitory neurons fire at much

higher rates than the excitatory pyramidal neurons (reviewed in Connors and Gutnick, 1990). The fact that inhibitory neurons make much more contacts on or near the cell bodies is also important since the spatial location of a synapse determines its relative contribution to the electrical state of the cell (i.e., the closer the synapse to the site of generation of action potentials, presumably the axon hillock, the greater its effect). Therefore, the inhibitory system, by way of its distribution and pattern of activity, can efficiently balance excitatory neurotransmission in the cerebral cortex. The inhibitory system is also in a position to exert a very focused effect on a single excitatory input, since some dendritic spines receive both an excitatory and inhibitory synapse (Jones and Powell, 1969; Qian and Sejnowski, 1990). In this case, the interaction between the two synaptic inputs would occur locally, at the level of the dendritic spine that is relatively isolated from the rest of the neuron.

It thus becomes clear that studying the distribution and physiology of the excitatory and inhibitory synapses, as well as their development and plasticity, is essential for understanding the overall organization and functioning of the brain.

EXISTENTIAL PSYCHOLOGY

Existential psychology assumes that the meaning of one's life derives from the accumulation of decisions one makes. Everything one does involves making a decision, whether one recognizes it or not. Decisions involve mental and action components. Mentally, when one mulls over and reaches conclusions about experiences through the processes of symbolization, imagination, and judgment, decisions are being made. And when one takes action based on these mental processes, decisions are also being made.

Although decisions vary enormously in magnitude and content, they all share an invariant form, namely, one can choose the future or the past. Choosing the future involves striking out in a new direction, whereas choosing the past involves shrinking back into what is familiar and already known. Choosing the future regularly is the way of personal growth and development through new experiences that provide a continual sense of vibrant, unfolding meaning. Ongoing new experiences also satisfy the constant stimulation needs of the huge human brain, needs that have evolved over the centuries.

Given all this, why would anyone characteristically avoid choosing the future? The reason is that choosing the future brings with it ontological anxiety, or fear of uncertainty and failure. One cannot be sure whether what transpires will be pleasurable, effective, successful, or what one hoped for. If what happens is positive, that will further your self-esteem, but if it is negative, you will have no one to blame but yourself.

Choosing the past, however, is not really a viable alternative, because it arouses ontological guilt, or the sense of missed opportunity. If one chooses the past regularly, one declines to mull over experience to see what it might involve, preferring instead to categorize it in old, established ways. Further, choosing the past involves taking only routine, habitual actions, regardless of the circumstances. If this process continues, the resulting sense of missed opportunities understandably accumulates into boredom,

stagnation, bitterness, and meaninglessness. The eventual outcome is the conclusion that life is not worthwhile and that you are inconsequential. Further, choosing the past characteristically will be a constant source of frustration to that huge human brain, so needy of the new information that comes through symbolization, imagination, judgment, and novel action.

Needless to say, the most authentic way of life is regularly to choose the future, despite the ontological anxiety this brings. To do this well, one needs existential courage, or the recognition and acceptance that growth and development is not only a vibrant but also a painful experience. Existential courage has been operationalized as hardiness, which is a motivational set of attitudes comprising the three Cs of challenge, commitment, and control. Persons strong in challenge see change as normal and something to be learned from rather than a threat to be avoided. They do not expect easy comfort and security in life. Persons strong in commitment are inclined to stay involved with the people and events around them, seeing this as the most interesting and worthwhile way. They see withdrawal into isolation as a waste of time. Persons strong in control keep trying to influence the outcomes of which they are part, and they feel that sinking into powerlessness is too easy a way out.

As existential courage, hardiness (1) is not considered inborn, but rather is learned through encouragement to struggle with stresses, and (2) leads to resiliency, such that there is not only survival but also enhancement of performance and health under stress. Accumulating research findings provide support for these hypotheses. In this research, a wide range of stressful contexts have been used, from life-threatening events of military combat, through the culture shock of immigration or work missions abroad, to everyday work, school, or sports pressures and demands. Across such contexts, hardiness leads to enhanced performance, leadership, conduct, morale, stamina, and health. Further, the early lives of people strong in hardiness are characterized not only by many ongoing stresses, but also by being designated by their parents as the family's hope and having accepted that role.

In adulthood, the personality type resulting from regularly choosing the future is called *authenticity,* or individualism. Characteristics of this type include defining (1) oneself as someone who can, through decision making and interpretation, influence ongoing experiencing, and (2) society as formed out of the actions of individuals and, therefore, changeable by them. Authentic persons can learn by failures, and their lifestyle shows unity and innovativeness. Their biological and social experiencing shows subtlety, taste, intimacy, and love. Because of hardiness, doubt (ontological anxiety) is regarded as a natural concomitant of creating meaning and does not undermine the decision-making process. Although authentic people can fall into self-deception, they tend to correct this rapidly through their commitment to self-scrutiny and reflectiveness.

In contrast, the personality type resulting from regularly choosing the past is the conformist. This type is characterized by defining (1) oneself as nothing more than a player of social roles, and (2) society as an unchangeable, incontrovertible source of meaning and rules. Expression of symbolization, imagination, and judgment is inhibited, leading to stereotypic, fragmentary functioning. Biological and social experiencing is unsubtle and contractual, rather than discerning and intimate. Conformists feel worthless and insecure because of the buildup of ontological guilt through choosing the past rather than the future. Their worldview emphasizes materialism and pragmatism, and they deny and persist in failures rather than learning from them.

These two personality types refer to everyday functioning, rather than expressions of psychopathology. Existential psychology defines psychopathology in terms of massive breakdowns of one's everyday functioning, precipitated by major stresses. These major stresses are of three sorts, namely, experiencing significant social upheavals, life-threatening circumstances, and unavoidable and insistent indications of personal superficiality. Conformists are especially vulnerable to these major stresses, whereas individualists tend to use them as springboards to further growth and development. The most extreme form of psychopathology resulting from the breakdown of the conformist lifestyle in reaction to major stresses is *vegetativeness,* which is characterized by the inability to believe in the value of anything one can do or imagine doing, constant boredom, and actions that are listless and aimless. A less extreme form of existential psychopathology is *nihilism,* characterized by the sole cogency of paradoxical (or anti) meaning, feelings of anger and disgust, and the pursuit of hurtful actions against any positive meaning and those who believe in it. Least extreme is the psychopathology of *adventurousness,* wherein only extreme or dangerous activities retain any meaningfulness, and there are resulting wide swings in mood and action as the person tries to avoid everyday circumstances and pursue more dramatic experiences.

EXIT INTERVIEWS

Exit interviews are used in employment settings, focusing specifically on those employees who are leaving the organization. Two distinct purposes can be identified for such interviews: information gathering and information giving. In addition, the exit interview can be a good way to show support for the departing employee's decision or to stay in touch with employees after they leave.

Information gathering is an attempt to curb financial

losses associated with excessive turnover and to collect diagnostic information regarding organizational functioning. Why are employees seeking other jobs? Are departing employees the best or worst workers? In contrast, information given to employees helps smooth their transition. An employee may wonder, for example, what the status of his or her benefits is. This is also an opportunity for the employer to make certain that the employee has checked in all keys and other company property.

Maintaining good relations with past employees is a more recent consideration in the literature on the exit interview, but in an era of declining employee loyalty to organizations, it is always possible to have an employee work in or around the organization again, either as a rehire or as an employee of an organization that does business with the former employer. The value of exit interviews is open to question. Research has shown that these interviews and a later follow-up questionnaire gave different reasons for leaving, with questionnaire results being more negative toward the company. The same general results have been found in a study comparing exit interviews to results obtained by an interview with an outside consultant.

Perhaps the best time to collect information (e.g., "What would it take to get you to consider employment elsewhere?" "Why do you stay here?") is before the decision is made to leave, or 6 months after the employee has left. At the actual time of departure, the employee may well not give accurate or honest information, because he or she is emotionally elsewhere—the new job. In short, employees may be reluctant to help the employer.

In spite of such problems, exit interviews should be used. In order for them to be effective, the organization should carefully consider the information to be gathered, who should be doing the interview, how that interviewer should be prepared for the task, and what kinds of organizational support are required (Finney, 1999). Interpretation of any information obtained should carefully consider biases, but ignoring the problem altogether is not a generally preferable alternative.

EXORCISM

An exorcism is a ritual, formalized by the Catholic Church during the seventeenth century, performed on a person exhibiting signs of demonic possession. Possession is said to occur when the Devil enters and takes over the physical and mental faculties of the victim. The purpose of exorcism is to remove the Devil from the possessed person. This ritual, described in the *Ritual Romanum* in 1614 and still accepted as the official procedure, was directed at the Devil or "unclean spirit" assumed to inhabit the body of the possessed. One of the most popular and dramatic explanations of disordered behavior, demonic possession was mentioned only once in the Old Testament of the Bible. Possession, however, is referred to frequently in the New Testament of the Bible. The possessed person may be either an innocent victim or targeted by the Devil because of previous evil behavior. Four complete cases of exorcism were reported to have been performed by Jesus. Explanations relying on demonic possession have been reported in most countries at various times throughout history.

Accepted signs of demonic possession may include any of the following: an offensive stench, tight lips, inability to pray, the vomiting of strange objects, rolling of the eyes, the display of powers beyond one's physical capacity, the shouting of obscenities, personality changes, prophetic wisdom, convulsions, the capacity to speak or understand a strange language, repulsion by the sight of the cross, repulsion by holy water, and the refusal to enter a sanctified place of worship. Most of those persons found possessed were women.

During the early Christian era, exorcistic skills were considered to be a special talent. Later, during the middle of the third century, the Catholic Church created the position of exorcist. The exorcist was typically a minor cleric who exhibited the necessary piety, judgment, and character for the position. Exorcism consisted of two parts. First, the exorcist strengthened himself by praying. The Devil was subsequently attacked, insulted, and commanded to leave the body of the possessed. Recovery was assumed to have occurred when the person returned to a prepossessed state. Contemporary Roman Catholic belief distinguishes between major and minor exorcisms, depending upon the degree of possession. A brief exorcistic rite is often included in the baptismal ceremony of the Catholic Church. The Catholic Church updated the guidelines for exorcism in 1999. The new guidelines encourage making a thorough medical and psychological evaluation before recommending an exorcism. The psychological literature regarding exorcisms is limited primarily to case studies and anecdotal reports.

EXPERIENTIAL PSYCHOTHERAPY

Experiential therapy refers to a way of conducting therapy rather than to a therapy specific to one theory of persons or

personality. Experiential therapy comprises a method for applying theory, and in this way it is metatheoretical.

A central focus in conducting therapy experientially is the client's moment-to-moment experiencing. Experiencing is seen as the entry point to processes leading to personality change and psychological improvement. It is the primary navigational aid regarding a productive course of therapeutic interaction.

Therapeutic moves (empathic response, interpretation, suggestion, question, confrontation, chair work, psychoeducation, etc.) can be immediately evaluated by their effect on client experiencing: When subsequent experiencing becomes more closed, defensive, abstract, or out of control for the client, the move has had an experiential effect of dubious value. When experiencing becomes more open, emotional, complex, intricate, sensation based, and accurately expressible in words or other symbols, the move has had a desirable experiential effect.

Attending to this experiential feedback protects the therapist against the pitfall of selectively perceiving data anticipated by the therapist's particular theoretical or personal expectations. The experiential therapist can thereby quickly correct unhelpful moves, rather than persisting with faulty plans and generating problems in the therapeutic relationship.

References to the experiential way of doing therapy are found in the works of many major early psychotherapists. Carl Rogers developed a method of psychotherapy in which client experiencing is centrally relied upon to guide the course of therapy, as counterpoint to the widely held belief that the doctor should guide the therapy. Carl Whitaker and T. P. Malone may have been the first to use the term *experiential psychotherapy* to describe their approach. Eugene Gendlin, who worked closely with Rogers, developed the philosophical basis that makes systematic the experiential method. Gendlin cites the existential and phenomenological philosophers S. Kirkegaard, W. Dilthey, E. Husserl, M. Heidegger, M. Buber, J.-P. Sartre, and M. Merleau-Ponty as precursors of his experiential philosophy.

Rogers drew on biologist Kurt Goldstein's observation and conceptualization of an actualizing tendency. This is the tendency, found in any living organism, to behave in ways that fulfill and further perfect the capacities, according to its nature, of the organism as a whole.

The client's moment-to-moment experiencing is seen as the real-time expression of the actualizing tendency. Experiencing is wider and deeper than conscious experience. Subjectively, experiencing is found in the person's "inner space." It is generally vague and and often elusive, with physical sensations and emotional qualities attendant to relevant cognition. This inner sense of intricacy is called the *bodily felt sense.* Experiencing is considered inherently life-promoting for both the individual and the social group, and generally more so with more awareness.

The actualization of healthy potentials implicit in experiencing does not depend only on the individual, but is seen as highly dependent on the interpersonal (and other environmental) conditions with which the person interacts currently and with which the person has interacted historically.

Things go awry when factors in a person's environment interfere with healthy awareness and symbolization of experiencing that would carry it forward to meet the person's needs, especially if the interference is systematic over a long time. Certain patterns of relating to experiencing (or avoiding it) may result; these patterns shape the positive potential of experiencing into negative and ineffective forms of expression.

Therapy, then, is very much about changing problematic attitudes toward experiencing. The therapeutic relationship establishes a safe climate within which, aided by the expertise of the therapist, the client can better articulate, express, and live out experiencing. The process of doing this takes time and involves many little successes before major and lasting change is accomplished. When something in experiencing that has been poorly symbolized is finally approached with an empathic attitude that results in more accurate symbolization, there is a bodily sigh of relief known as a *felt shift.*

When a person regularly and reliably relates to experiencing so as to get these felt shifts, he or she is said to have a high level of experiencing. There is evidence that a high-experiencing way of working with one's feeling about a traumatic experience has a positive effect on physical health, in the form of improved immune function. Many studies have found psychological benefits associated with high levels of experiencing.

Regardless of his or her theoretical training, the experiential therapist remains alert for the words, images, behavioral strategies, or situational changes that have a positive resonating power with the client's bodily felt sense. Thus many different approaches to helping the client are usable, limited only by what the therapist knows and can work with skillfully. Therapist and client both rely on responses from their body senses to the steps of therapeutic interaction in order to guide the way toward improvement that is both uniquely right for the client and in the theoretically and interpersonally desirable direction.

EXPERIMENTAL CONTROLS

Edwin G. Boring (1954) developed three meanings in psychology for the word *control:* (1) a check, in the sense of verification; (2) a restraint, in the sense of maintaining constancy; and (3) a guide or direction. Controlled observations, and controls on experimental variables or checks on

observations, are as old as science. The use in psychology, however, of an experimental control group as such—a separate group of individuals against which comparisons of the experimental group's observations are made—began during the twentieth century.

Since people not in psychological experiments do learn, mature, and change from experiences in daily living, experimental control groups for comparison purposes are valuable, almost necessary, in most of psychology in order to have a context in which to interpret meaningful research findings. In addition, the almost inherent lack of ability to measure with precision in psychology has a decided influence on changes in observations over time. The research context in which the observations are made, the possible reaction of participants to the somewhat unusual conditions of the psychological research study, and motivational differences between the experimental and control groups can also reduce the quality of the comparisons needed for interpretation. These concerns are also the subject of experimental design and research methodology.

Early attempts to develop experimental controls in psychological research included attempting to hold all variables constant except those being deliberately manipulated. This is difficult to do with human participants; it can be done only within rather broad limits, and it often makes the experimental conditions so artificial that generalizations to the everyday psychological world are difficult.

Participants in psychological research are sometimes used as their own experimental controls; they are observed, an experimental condition is applied, and then they are observed again. This method is useful if a large number of observations are made prior to and after the experimental condition. Such observations can be used to establish the stability of the participants' behavior and its typical range. When the experimental treatment can be applied and withdrawn over time—again with many observations made in each interval between conditions—the experimental control is better. If a stable change can be observed after each of the conditions, then good comparisons and interpretations can be made.

In psychology, experimenters often match participants on one or more variables or group participants by characteristics or prior conditions. Then some of these groups have the experimental treatment and some do not. If the groups are matched on variables such as gender, residential area, or other accurately observed characteristics, the method is acceptable. If the matching or grouping can be followed by a chance allocation of participants (i.e., at random) to experimental and control groups, the resulting experimental controls and comparisons are quite good. If not, there can be major errors.

Sometimes statistical adjustments are attempted as a control method in psychological research. Unless accompanied by allocation of participants to experimental and control groups by chance, these methods often are less than adequate to obtain good research comparisons.

During this century psychology has developed a rather mature, rigorous, and sometimes elaborate set of experimental controls for its research methodology, taking into account the special characteristics and problems associated with human participants and psychological variables. Its research methodology is still growing, however, and undoubtedly more and better experimental controls will be developed.

EXPERIMENTAL METHODS

Experimental methods are among the scientific methods used in psychological research. True experiments involve the careful observation of the effects of one or more variables (independent variables) on one or more outcome variables (dependent variables) under carefully controlled conditions with subjects randomly assigned to treatments. For example, a study of the effect of adrenaline on activity level could be done by randomly assigning subjects to an experimental group (who receive adrenaline) or to a control group (who receive an inert substance, a placebo) and then recording their activity levels in an objective way. The independent variable (drug dosage) has two levels (drug vs. placebo), and the dependent variable (activity level) is measured using an operational definition (a description of how activity level scores are assigned). More levels of the independent variable could be used; for example, subjects might be given 0-mg, 3-mg, 10-mg, or 25-mg doses of adrenaline, so that the independent variable would have four levels.

The experiment could be made more complex by adding additional independent or dependent variables. For example, time of day might be used as a second independent variable with three levels (morning, afternoon, evening), so that subjects might be randomly assigned to any of 12 different conditions (0 mg in the morning, 10 mg in the evening, etc.). It is clear that the number of subjects required for more complex designs would be greater than for simpler designs because the number of subjects under each condition (e.g., 10 mg in the afternoon) must be sufficient to generalize about that condition.

Although other scientific methods exist, the true experiment is the only method that allows researchers to make conclusions about cause-and-effect relationships. In the simple experiment with one independent variable (drug dosage) with two levels, if subjects in both the experimental and the control group are treated in identical ways (except for the independent variable), and if subjects are randomly assigned to treatment conditions (drug vs. placebo),

then any differences between the activity level scores can be attributed to the independent variable. To infer causation, it is essential that the subject groups not differ with respect to anything other than the independent variable. For example, if only men were in the experimental group and only women were in the control group, observed differences might reflect gender rather than dosage differences.

Sometimes independent variables cannot be manipulated by the researcher. For example, a researcher with gender, ethnicity, political party, frequency of marijuana use, or educational level as an independent variable cannot randomly assign subjects to levels of independent variables. Such variables sometimes are called *nonmanipulated variables.* The study of such variables cannot make use of a true experiment, but they are frequently studied in quasi-experiments. Interpretation of results for nonmanipulated variables is complicated, since various additional variables generally are confounded with them. For example, social class, intelligence, and a number of personality variables are confounded with educational level, so observed difference between high school and college graduates may reflect these confounded variables rather than the effect of education. One way to facilitate interpretation of nonmanipulated independent variables is to match subjects on relevant confounding variables. For example, each high school graduate could be paired with a college graduate who matches in age, gender, social class, intelligence, and personality measures. The more complete the matching, the more comfortable the researcher can be in interpreting the effects of the independent variable.

Sometimes research strategies involve repeatedly testing the same subjects. A longitudinal study of human development may test the same group of children at ages 2, 5, 10, and 20, or a learning study may test subjects after every stimulus presentation. This introduces another complication: an order effect. For example, if subjects are asked to rate the physical attractiveness of 10 people, with slides showing the stimuli presented to all subjects in the same order, the rating of the third slide may reflect an order effect as well as the stimulus. If the second slide, for example, is of a particularly attractive person, the third slide may be undervalued because of a contrast effect. If the third slide were in a different ordinal position, its ratings would be different. Clearly, the solution to such problems involves manipulation of the order, so that different subjects receive the stimuli in different sequences. This is the technique of *counterbalancing.*

Experimental designs vary across experiments and depend upon a number of factors: the number of independent and dependent variables; whether independent variables are manipulated or nonmanipulated; whether subjects are matched or tested once or repeatedly; and how subjects are assigned to experimental conditions.

All experimental methods must be used carefully and cautiously, with attention to ethical, practical, and statistical considerations. Scientific theory is built upon repeated, consistent research results; a single study represents only one piece of information for scientific evaluation.

EXPERT TESTIMONY

It has been over a century since lively debate began in scientific journals and law reviews on the psychology of testimony and the value of psychology to the judicial process (Goldofski, 1904; Jaffe, 1903; Lobsien, 1904). Hugo Munsterberg brought together a number of essays on psychology and crime, first publishing these in the *New York Times* magazine and then as the book *On the Witness Stand* (1908). In his enthusiasm Munsterberg stated, “my only purpose is to turn the attention of serious men to an absurdly neglected field which demands the full attention of the social community.” He then presented a series of essays on illusions, the memory of witnesses, the detection of crime, untrue confessions, hypnotism and crime, and the prevention of crime.

Munsterberg’s effort was interesting, enthusiastic, and predictive of the increasing overlap of psychology and law. It was, unfortunately, somewhat premature, but it did not go unnoticed. John H. Wigmore, professor of the Law of Evidence at Northwestern University, wrote a scathing parody of *On the Witness Stand* that was published in the *Illinois Law Review* in 1909. The critique reported a mythical suit filed in the city of “Windyville, Illiania” against Munsterberg for having “caused to be printed, published, and circulated in Illiania and throughout the country . . . [a book that] contained . . . certain assertions, erroneous, incorrect and untrue concerning the said plaintiffs, in their capacity as members of the bar.”

Wigmore confronted Munsterberg with the lack of published evidence to support the claim that the law was ready for psychology, as Munsterberg had cited no references in his pioneer text. The mock complaint cited 127 learned treatises to justify the proceedings. The mock trial ended with a finding against Munsterberg, the jury assessing damages of one dollar.

Wigmore’s attack was telling: Few references to psychologists as expert witnesses appeared for a quarter of a century. Then in 1931 Lewis M. Terman, a professor of psychology at Stanford University, appeared before the Los Angeles Bar Association to present an address, “Psychology and the Law.” Terman took pains to refer to Munsterberg’s

On the Witness Stand and Wigmore's scathing response. He suggested that Munsterberg's error was in exaggerating the importance of psychology's contributions based on the then-existing research. Termin indicated, however, that the ultimate significance of psychology for the legal profession could hardly be overstated considering the scientific advances made during the first quarter of the century. Terman emphasized the value of experimental psychology in clarifying errors of testimony. He suggested psychology may be useful in developing, researching, evaluating, or clarifying lie detection, eyewitness testimony, the vagaries of the insanity plea, and jury selection. Terman ended his presentation with a critique similar to that presented by Hugo Munsterberg nearly a quarter of a century before: "Our law, like our proverbs and adages, are the product of folk-thinking and like those, they are a mixture of shred wisdom, childish error, superstition, and folly" (Terman, 1935).

By this time, Wigmore's *On Evidence* was considered the definitive work, as it was being used and cited by attorneys and judges throughout the United States. Yet psychology's most bitter critic in the law at that time modified his position in the last edition of his master work: "Both law and practice permit the calling of any expert scientist whose method is acknowledged in his science to be a sound and trustworthy one. Whenever the Psychologist is ready for the Courts, the Courts are ready for him" (Wigmore, 1937). Clearly, Wigmore was demonstrating the flexibility, awareness, and practicality psychologists are likely to find among lawyers and judges when presented with psychological data, techniques, and methods generally acceptable to colleagues and concordant with the standards of the profession.

One of the earliest reviews of the legal and psychological literature regarding the psychologist as expert witness was published by D. W. Louisell in 1955. An appendix to this article presented the testimony of Dr. Kenneth E. Clark in the trademark infringement case of *Robinsdale Amusement Co. v. Warner Brothers Pictures Distributing Corp. et al.;* Clark testified as an expert in public opinion techniques.

During the 1950s psychologists were sometimes qualified as experts and sometimes dismissed by the judge. In 1954, Dr. Michael H. P. Finn, then chief psychologist at the Springfield State Hospital, appeared in *Hidden v. Mutual Life Insurance of New York.* The judge refused to allow Finn to testify. On appeal, the U.S. Court of Appeals reversed this decision on the ground that Finn was qualified to give expert testimony.

In the earliest formal text on private practice in clinical psychology, T. G. Blau (1959) included a chapter entitled "The Clinical Psychologist and the Legal Profession." Blau suggested that psychologists would do well to prepare themselves to be competent expert witnesses within their field. Several court transcripts were included to illustrate direct examination and cross-examination of psychologists in personal injury and competency cases.

The role of the psychologist as expert witness in matters of mental disease or defect was addressed in considerable detail in the landmark case of *Jenkins v. United States* in 1962. After indictment for housebreaking with intent to commit an assault, assault with intent to rape, and assault with a dangerous weapon, Jenkins was committed to a hospital in Washington, D.C., for a mental examination on September 4, 1959. The purpose of the examination was to determine his competence to stand trial and his mental state at the time of the alleged offense. Jenkins was given a series of psychological tests by staff psychologists under the supervision of Bernard I. Levy. Jenkins was also examined by several psychiatrists, who informed the District Court that he was incompetent. He was then committed to St. Elizabeth's Hospital until mentally competent to stand trial. At St. Elizabeth's he was tested extensively by Lawrence Tirnauer, PhD, who concluded Jenkins was schizophrenic. Two other psychiatrists found "no evidence of mental disease or defect." Margaret Ives, PhD, administered additional tests and concluded that Tirnauer's diagnosis was correct. The trial court, *sua sponte* (on its own motion), instructed the jury to disregard the testimony of the three defense psychologists' opinions that the defendant had had a mental disease when allegedly committing the crimes.

On appeal, Judge Bazelon of the U.S. Court of Appeals held that the lower court had erred on several points, including rejection of qualified psychologists as experts on the presence or absence of mental disease. This decision was rendered in spite of an *amicus curiae* brief submitted by the American Psychiatric Association, urging the court not to allow psychologists to qualify as experts. Bazelon's scholarly opinion defined the fully trained psychologist. In a rare concurrence, Judge Warren Burger (who later became a Chief Justice of the U.S. Supreme Court) agreed with Bazelon. Since the *Jenkins* decision, the rejection of psychologists by the court as experts in their fields of specialization has been considered trial error.

Not all psychologists are likely to be accepted by the court as expert witnesses in all areas of psychological practice. The psychologist must be qualified before the court as an expert in the area about which he or she will testify. Furthermore, as legal scholars have pointed out, the issue must be such that the expert may answer by giving an opinion that is a reasonable probability, rather than conjecture or speculation (Ladd, 1952).

The credibility of any expert's testimony in some jurisdictions continues to follow the admonition delineated in *Frye v. United States* (1923), in which the court reasoned:

> Just when a scientific principle of discovery crosses the line between the experimental and demonstrable stages is difficult to define. Somewhere in this twilight zone the evidential force of the principle must be recognized, and while courts will go a long way in admitting expert testimony deduced from a well-recognized scientific principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field which it belongs.

The admissibility of expert testimony was predicted to change drastically subsequent to the 1993 case *Daubert v. Merrell-Dow Pharmaceuticals.* A majority opinion by the U.S. Supreme Court indicated that the *Frye* test was too austere and that a new standard based on the Federal Rules of Evidence should be adopted. Admissibility of testimony based on the Federal Rules of Evidence tended to be more flexible than the *Frye* rule. It indicated that a qualified expert could provide scientific, technical, or specified knowledge that would assist the trier of fact or law in determining an issue that was based on material that was reliably accepted by the scientific community. The *Daubert* ruling basically made the trial judge the gatekeeper to the admissibility of expert testimony. Several criteria were enumerated by Justice Blackman for trial judges to use in determining the admissibility of testimony, and include (1) whether the hypothesis that formed the basis for the testimony was testable (falsifiability), (2) whether it had been published, (3) whether there was a known error rate for the procedure, (4) whether it had been peer-reviewed, and (5) whether it was generally accepted in the field. Interestingly, the *Frye* test of whether a particular scientific principle is "generally accepted in the relevant scientific community" bears considerable similarity to the last criterion enumerated in *Daubert* regarding whether such a principle is generally accepted in the field.

In 1999, the trial judge's gatekeeper status was reaffirmed by the U.S. Supreme Court in the case of *Kumho Tire Company v. Carmichael.* The Supreme Court upheld exclusion of testimony based on the unreliability of the methodology.

The Revised Ethical Principles of Psychologists and Code of Conduct (American Psychological Association, 1992) addresses forensic activities. Specialty guidelines for forensic psychologists published in 1991 by the Committee on Ethical Guidelines for Forensic Psychologists more specifically address the ethical obligations of psychologists providing expert testimony.

Since the *Jenkins* decision, psychologists have appeared more frequently in the courts as experts. Most published reports of psychologists as expert witnesses involve competency evaluations and the sanity plea. In this narrow area of expert testimony, psychologists have entered into a domain once belonging exclusively to psychiatrists. Data suggest that psychologists are successful and well regarded as expert witnesses in matters of competence and sanity (Perlin, 1980). Psychologists testify in civil matters, including personal injury, wrongful death, trademark infringement, product liability, and other issues. Psychologists have testified in criminal courts in matters of change of venue, death-qualified juries, prison conditions, and capacity to form criminal intent.

Judges are increasingly aware of the potential of psychologists to assist the courts. Patricia McGowan Wald (1982), circuit judge for the U.S. Court of Appeals, District of Columbia, has stated: "I find that after a decade or more of increasing awareness among psychologists and lawyers about what litigation can and cannot accomplish, the era of their most productive relationships built on mutual respect and realistic idealism may be only just beginning."

More graduate and postgraduate training is being offered to prepare psychologists to function as expert witnesses in the courts. Psychologists who currently expect to function in this role must acquire education, training, and experience ad lib or, more appropriately, from continuing education at the postdoctoral level. Interest in this area is burgeoning; it seems likely that doctoral students in professional training programs will, in the future, have a greater opportunity to prepare to function as experts for the courts. Joint PhD/JD programs are producing psychologist-lawyers who, one hopes, will bridge the gap of knowledge and issues of mutual distrust between the two professions (Wolinksy, 1982).

One way to assess the importance of appropriately given expert testimony is by the number of books and chapters dedicated thereto. The interested reader is referred to the Suggested Reading section that follows.

EXTRASENSORY PERCEPTION (ESP)

Awareness of information that occurs independently of known sensory channels such as sight, hearing, taste, smell, or touch, is referred to as *extrasensory perception* (ESP). Examples of ESP claims include the detection of hidden objects (clairvoyance), thought transference between people (telepathy), and knowledge of future events (precognition). Some experiences may give the appearance of extrasensory awareness, yet ESP phenomena require scientific support to verify their authenticity (Irwin, 1999). Historically, anecdotes of spontaneous cases of anomalous experiences constituted the basis of ESP claims. *Spontaneous cases* are subjective reports of everyday life experiences categorized in terms of clairvoyance, telepathy, or precognition (L. E. Rhine, 1953). When distinctions between clairvoyance, telepathy, and precognition became ambiguous, the concept known as *general extrasensory perception* (GESP) was proposed by Joseph B. Rhine (1948), an American pioneer in conducting research on ESP. Moreover, the term *psi* embraces both ESP and psychokinesis (PK), that is, mental influence on physical events ("mind over matter"; Schmidt, 1973). Concerns over the precision and proliferation of terminology in ESP have persisted for over a century (Zingrone & Alvarado, 1987).

Rhine's Research Efforts at Duke University

Joseph Banks Rhine was a botanist who joined the faculty at Duke University in 1927. In 1934, Rhine published a monograph based on his laboratory studies, entitled *Extra-Sensory Perception,* in which he claimed overwhelming statistical evidence for the existence of ESP. These lab studies conducted by Rhine were empirical in design, and his data were statistically analyzed, which provided greater objectivity compared to the spontaneous-case approach. Yet Rhine's observations were not experimental because his research did not employ control groups or conditions. ESP research continued at Duke until 1962 when Rhine reestablished his laboratory in Durham, North Carolina, close to the campus. Rhine called his new location the Foundation for Research on the Nature of Man (FRNM), and it is now referred to as the Rhine Research Center.

Learning to Use ESP with Automation?

Principles of conditioning and learning models in psychology have been applied to the possibility of teaching people to increase their ESP skills. Giving immediate feedback to subjects after each trial has led to a reduction in the *decline effect* (a gradual decrease in the number of hits over many series of tests), yet these scores are not consistently above chance (Tart, 1976). Attempts to automate ESP research designs and rid them of extraneous sources of physical cues called *sensory leakage* prompted the use of computers (Broughton, 1982). Moreover, useful control tests can be done with a computer (Gaither & Zusne as cited in Zusne & Jones, 1982).

Remote Viewing Experiments

The Stanford Research Institute (SRI) conducted a series of experiments to determine whether subjects could accurately describe a randomly selected outdoor location that was at a distance and not visible from the subject's laboratory room (Targ & Puthoff, 1978). The Central Intelligence Agency financed an independent study of possible uses of remote viewing, such as for governmental spying, only to abandon this program in the late 1970s in the absence of encouraging findings (Hyman, 1996). Suggestions of methodological and statistical flaws and concerns that the judges of subjects' reports were not totally ignorant of the identity of the target locations cast doubt on the validity of remote-viewing data (Irwin, 1999).

Beliefs in the Existence of ESP

The term *sheep* was chosen to refer to people who believe in the possibility of ESP and *goats* refers to those who doubt or deny its existence (Schmeidler & McConnell, 1958; Thalbourne & Delin, 1993). The persistence of belief in the ex-

istence of ESP despite only occasional hits compared with the many trials of failure reported in controlled lab research has been analyzed. Rationales for such tenacity of belief include the cognitive need for people to structure many puzzling events in life so that they appear comprehensible (Irwin, 1999) and the *partial reinforcement effect,* in which occasional hits of ESP hidden targets compared to numerous misses result in a strong "resistance to extinction" of ESP beliefs (Vitulli, 1997).

Future Status of Research and Theory in ESP

The *ganzfeld* procedure deprives the subject of normal sensory stimulation (Bem and Honorton, 2001). ESP-conducive data have been reported under *ganzfeld,* yet apparent methodological flaws result in controversial interpretations. Scientific theories are characterized as having aesthetic value or beauty in rough proportion to the degree of empirical data in support of that theory (McAllister, 1998). The absence of reliable demonstrations, upon demand, of the existence of ESP leaves this area of inquiry in a state of limbo. Nevertheless, the spirit of human curiosity serves as a beacon for scientific progress. Despite paranormal claims, research in anomalous experiences such as ESP continues to occur for the sake of knowledge, regardless of where it may lead.

EXTRAVERSION AND INTROVERSION, CONCEPT OF

The words *extraversion* and *introversion* have been in use for several centuries. Considered etymologically, they may be construed respectively as an "outward turning" and an "inward turning." They have been used, in fact, with essentially those meanings, both in a physical sense and in a psychological sense. The psychological usage can be found in writings dating as far back as the seventeenth century, where extraversion referred to the turning of thoughts toward outer objects and introversion referred to the turning of thoughts inward to one's own mind or soul or to the spiritual realm.

The work of Jung (1921/1976) is largely responsible for directing the attention of psychologists to these concepts. Jung viewed extraversion versus introversion as the most basic dimension of human temperament and believed many major fluctuations and controversies in Western thought could be understood in terms of a clash between these opposing outlooks. He also believed that Western thought on the whole, in comparison with that of the Orient, stressed extraversion.

Jung defined extraversion as an outward turning of libido, or psychic energy. This is equivalent to saying that extraversion means a directing of interest toward objects

(other people or things) in the environment and functioning in relation to those objects. In an extraverted state one perceives, thinks, feels, and acts in relation to the object. We might also say that action and experience are determined directly by the object. Introversion is defined as an inward turning of libido. This implies a directing of interest away from the object toward the subject—toward the individual's own conscious experience. In an introverted state, perception, thinking, feeling, and action are determined more directly by subjective factors than by the object. The extravert, the individual who is habitually in an extraverted state, tends to respond immediately and directly to stimuli from without. Habitually in an introverted state, the introvert tends to withhold immediate responses and act on the basis of subjective considerations that follow the external stimulus.

Jung (1921/1976) reviewed a variety of earlier dichotomous typologies and concluded that many of them represented equivalent expressions of the same basic dimension. He regarded hysteria and psychasthenia respectively as extraverted and introverted forms of psychoneurosis, and he suggested that manic-depressive psychosis and Schizophrenia represented a similar parallel in the realm of psychosis. He also concluded that the polarity of tough-minded versus tender-minded, which James (1907) applied to a basic division within the field of philosophy, was basically the same as his own dimension. It can be argued, however, that James's dimension is more concerned with ingredients of the psychic function dimensions described by Jung (thinking versus feeling and sensation versus intuition). There is evidence that the most basic division of perspectives evident in the histories of both philosophy and psychology is better characterized by the dimension postulated by James than by that of Jung (Coan, 1979). Many other theorists have proposed dichotomous typologies that involve some sort of inner-outer contrast, but it is a mistake to assume that these all involve the same underlying temperament dimension.

The dimension of extraversion versus introversion itself has been subject to a variety of interpretations. Upon learning of Jung's use of these terms, Freud concluded that extraversion was the healthy condition, while introversion constituted a predisposition to psychopathology. To Freud, an "inward turning of libido" implied narcissism, while an "outward turning of libido" implied the possibility of forming a true object-cathexis, hence the achievement of the genital level of development. Jung, however, did not construe extraversion and introversion in quite this way and considered neither to be preferable to the other. The Freudian perspective tends to prevail in any society, such as the United States, that favors extraversion over introversion.

There has been a tendency among American psychologists and educators to view extraversion as preferable and to reinterpret the dimension in terms of social behavior. Thus, extraversion has often been understood in terms of sociability, while introversion has been regarded as a tendency to withdraw from social contacts. Jung thought of the dimension primarily in terms of modes of experience or consciousness, and the behavioral definition itself reflects a more extraverted approach to psychology. Most efforts to construct questionnaire scales for the dimension reflect this shift in orientation, for the items have often contained extraversive scale content that pertains to sociability and introversive scale content that pertains to shyness, reserve, and anxiety. Even scales purported to measure the Jungian dimension usually focus on social behavior, because it is more difficult to formulate items that will evoke self-descriptions that directly express the variables conceptualized by Jung (Coan, 1978). A different method of assessment may be needed.

Murray (1938/1962) contended that Jung's concepts encompassed a number of component variables that might be distinguished and separately assessed. He suggested a component dimension of exocathection versus endocathection, which is concerned with the extent to which the individual attaches value to either the outer world or the inner world. He also posited a component dimension of extraception versus intraception. This is concerned with the extent to which perception, judgment, and action are governed either by observable, physical conditions or by subjective factors (feelings, fantasies, speculations, and aspirations).

Murray offered a rational analysis of Jung's concepts, but the work of some of the major factor-analytic researchers—including Cattell, Guilford, and Eysenck—indicates that semi-independent components of the extraversion-introversion dimension can be distinguished by statistical methods. These researchers concur in finding evidence for a broad general dimension of this sort, a dimension that enters into a large number of the specific individual differences we find in human personality. They differ in their identification and labeling of the components, but in the research findings of all three there is evidence of constituents of extraversion entailing such things as high activity level, sociability, impulsiveness, dominance, and dependence on the group. In contrast, such features as low activity level, deliberateness, and self-reliance are found to be associated with the introversive end of the dimension. Since the bulk of relevant factor-analytic research has focused on questionnaire responses, it is not surprising that the most obvious ingredients of the dimension lie in the realm of social behavior. In contrast, Murray's analysis remained closer to the polarity conceptualized by Jung.

Eysenck (1967) devoted particular attention to this dimension and, in interpreting it, borrowed a couple of physiological concepts from Pavlov. While studying temperamental variations among dogs, Pavlov concluded that some animals were characterized by a predominance of excitatory cortical processes, while others were characterized by a predominance of inhibitory cortical processes. Pavlov suggested a relationship between these processes and the four classical temperament types of Hippocrates and

Galen. Eysenck rejected Pavlov's rationale for this relationship, but he felt the process concepts could be used to explain the extraversion-introversion dimension. According to Eysenck, introverts are characterized by very sensitive cortical excitation processes. They tend, therefore, to feel intellectually and emotionally overwhelmed by moderate social and physical stimulation, and they are relatively prone to the experience of anxiety and despair. As a consequence, they often resort to a self-protective retreat from their surroundings and may limit interaction by means of self-control or behavioral inhibition. Extraverts are characterized by less sensitive cortical processes or by a predominance of inhibitory cortical processes. Consequently, they require more stimulation from the social environment and may actively seek it to overcome their own cortical inertia.

EYE

The eye performs three fundamental functions. Its optical components collect light energy. Its neural components transduce that light energy into electrochemical events and use these electrochemical events to produce meaningful neural signals that become the subjective sense of sight when further processed by the brain. All of the structures that make up the eye either contribute in some way to these functions or provide protection to the eye.

The protective tissue of the eye includes the lids and the transparent epithelial membrane known as the conjunctiva that lines the lids and continues to cover the white (sclera) of the eyeball. The tear or lacrimal glands and the fatty tissue of the orbit, which acts to absorb shock, also contribute protection to the eye.

The optical tissues of the eye include the cornea, the lens, the aqueous humor, and the vitreous humor or body. The cornea is the main structure responsible for refraction of light as it enters the eye. It normally does not have a blood supply. In addition to its refractive function, the cornea acts to protect the other optical structures of the eye and aids the sclera in giving the eye form and rigidity. The sclera is the tough white coat that forms the posterior four-fifths of the eye. The cornea is continuous with the sclera, and when the two structures are subjected to routine histological staining, the anatomical appearance of the cornea does not differ markedly from that of the sclera. The transparent quality of the cornea is due to a continual pumping of interstitial fluid across the cell surfaces, which prevents the cornea from becoming cloudy.

The lens of the eye lies behind the cornea and the pigmented iris. The lens is held in place by suspensory ligaments called the zonule fibers. The zonule fibers are connected to the ciliary body containing the ciliary muscle. When the ciliary muscle contracts, the lens bulges, thereby increasing the refraction of light. This happens, along with pupillary constriction and convergence of the eyes, as part of the accommodation reflex that occurs when an object close to the eyes is viewed. The image focused on the retina by the cornea and lens is upside down and reversed right to left.

The aqueous humor is secreted into the posterior chamber of the eye by epithelial cells that cover the ciliary body. Aqueous humor flows through the pupil to the anterior chamber of the eye, where it can exit the eye through the canals of Schlemm. Schlemm's canals are located in the angle of the anterior chamber where the iris contacts the cornea.

Both the posterior and anterior chambers of the eye lie in front of the lens and zonule fibers. The zonule fibers that encircle the lens consist of individual strands of connective tissue, and for this reason the fluid in the posterior chamber is in contact with the gelatinous substance called vitreous humor that fills the area of the eyeball between the lens and the retina. If the aqueous humor cannot drain through Schlemm's canals the resulting accumulation increases pressure within the eye, and this pressure is transmitted by the vitreous humor to the retina. This condition is called *glaucoma,* and the pressure on the retina can cause blindness.

The uvea, or vascular tunic, of the eye is composed of the iris, the ciliary body, and the choroid. The choroid is vascularized and pigmented. It lies between the retina and the sclera. Its pigmentation prevents the scattering of light in the eye. The iris lies posterior to the cornea and anterior to the lens. Light causes the iris to constrict. This reduces the amount of light that enters the eye but also enhances the depth of focus when the eye focuses on a near object. Thus, the iris constricts not only in response to increases in light but also as part of the accommodation reflex.

The retina is the photoreceptive and integrative portion of the eye. Embryologically, it is an outpouching of the surface of the brain. At the retina a light stimulus is converted into a neural code and transmitted over the optic nerve and tract to the brain. The neural organization of the retina is sufficiently complex to allow a fair amount of integration of visual information. The rods and cones are the photoreceptive cells of the retina and are located at the very back of the retina (i.e., in its most posterior aspect). The cones function during daylight and are responsible for color vision. The rods function best in dim light and present the world in shades of gray. Rods are most numerous in the periphery of the retina, while cones are concentrated toward the focal center. The fovea, or macula, is found in the focal center of the retina and contains only cones. The rods and cones make contact with the bipolar cells. In turn, the bipolar cells of the retina synapse with the ganglion cells. The ganglion cells give rise to axons which form the optic nerve. The point where all of the ganglion cell axons come together and leave the eye is called the papilla or optic nerve head. Because there are no receptors at this point, the papilla is a "blind spot" in the retina. Other neurons in the retina are associated with the bipolar layer and perform associative functions; they are known as horizontal and amacrine cells. The photoreceptive rods and cones are located behind the other retinal cells and the axons of the ganglion cells, such that light must pass through the axons, nonphotoreceptive neurons, and supporting glial cells before reaching the rods and cones.

The process of visual perception is initiated when light is absorbed by the photopigments contained within the outer segment of the rods and cones. Rhodopsin is contained within rods. The cones appear to utilize at least three separate photopigments, which have peak absorptions at wavelengths of light corresponding to the colors blue, green, and yellow. There is, however, considerable overlap in absorption among these pigments. Chemical changes initiated in the photopigments of the rods and cones when light is absorbed produce the rod and cone generator potentials.

EYE MOVEMENTS

The eyes are rarely stationary. To the viewer, the world seems quite stable and the eyes seem to be directed at will, but it is not so. Even when we intently view or fixate an object or scene, our eyes are free of large movements for only about 250 to 300 milliseconds, and fine movements are superimposed on even these seemingly stationary periods. Eye movements are generally functional in that they bring new information to central or foveal vision, and they change the scene so that receptors do not adapt and cease providing information to the visual cortex. Some eye movements such as fine tremors may be the result of muscle tension from the dense musculature servicing the visual system.

Each optical orbit is served by six muscles located in the medial aspect of the orbit. Anatomically they form three complement pairs. The medial rectus (nasal) and lateral rectus (temporal) allow for horizontal movement about the vertical axis. The superior rectus and inferior rectus provide practical complements for vertical movement, but they also have horizontal and torsional components allowing for oblique movement as well. The inferior and superior obliques, located slightly diagonal to one another, control torsional movements along with the superior and inferior rectus. Not only do these muscle groups provide for a great deal of latitude in movement, but their density also provides a greater amount of musculature for the weight of movable organs than does any other structure in the body. Consequently, there result great speed and great resiliency to fatigue.

Generally, the eyes move conjugately or in parallel; one exception is the vergence movement system, where the eyes move in opposite directions toward or away from the nose. Movements of the eyes are classified as catching, holding, and fine.

The next surge of interest in eye movements and reading came in the mid-1970s. Emphasis shifted to greater specificity on the parts of words on which the eye movements landed, and on the flexibility of eye movements to change dynamics between sentences within passages, based upon the reader's cognitive processing ability—that is, the perceived importance of text selections. Measuring devices have become much more comfortable, even though bite boards and head restraints are needed to achieve accuracy levels exceeding 1 min of arc and recording msec by msec. Other devices are aimed at more natural viewing with no encumbrances or awareness by the viewer, in order to get more naturalistic estimates of behavior with slight trade-offs in precision. Driving behavior, pilots' view of the ground and instruments, learning disabilities, psychopathologies, and many other areas of research interest involve recording of eye movements.

For nearly a century, principal empirical emphasis has been directed at verifying one of four proposed purposes for the eye movement sequence. First, eye movements may

maintain vision: Without them, receptors adapt, and scenes and pictures fade from view. Second, eye movements and their fixations may be responsible for perception: They seem to exhibit a psychomotor program directly related to a particular picture or scene that is viewed. Third, eye movements and their fixations may be directed by perception: Because fixations seem to fall in locations judged to contain high information, such as contours, objects, and shadings, it is believed that some overall semantic content directs the eye movement pattern. Fourth, the eye movement sequence may provide a means for the encoding, storing, and subsequent reconstruction of the successive retinal images of the detail found in a scene or picture: Each individual provides an idiosyncratic eye movement pattern as a reflection of that individual's own viewing and interpretation of the scene. The possibility also exists that all these alternatives at one time or another are correct.

EYSENCK PERSONALITY QUESTIONNAIRE

The Eysenck Personality Questionnaire–Revised Edition (EPQ-R) is the most recent version of the personality questionnaire designed to measure the three personality factors identified by Hans J. Eysenck (1916–1997) and others. These factors, known as psychoticism, extraversion, and neuroticism, comprise what is termed the P.E.N. Personality Model. The P.E.N. model holds that these three personality factors account for the bulk of human personality variation. That is, the model states that the personalities of humans differ primarily with respect to these three factors. Each personality factor is composed of a large number of specific traits. The EPQ-R is composed of 94 self-report items, such as "Do you like to arrive at appointments in plenty of time?" and "Do you worry a lot about your looks?" to which respondents either agree or disagree. The number of affirmative responses to items that compose each scale are summed to arrive at the scores on the three personality dimensions.

Individuals who have high scores on the Psychoticism subscale (27 items) have the potential to develop a psychotic disorder, as they may exhibit similar characteristics to those who have had a break with reality. These individuals may also have high levels of anger and are inclined to exhibit some types of conduct or behavioral disorders. They may be described as hostile or unempathic, and they may disregard societal conventions via nonconformity, recklessness, manipulation of others, and impulsivity. Other potential traits of people with high psychoticism scores include tough-mindedness, aggression, egocentrism, assertiveness, and dogmatism. Although there has been limited research on the biological basis of psychoticism, it has been suggested that these individuals have increased testosterone levels.

The Extraversion scale (22 items) measures one's level of sociability and affect. Individuals who have high scores on this subscale tend to be gregarious, carefree, and exciting. These individuals enjoy parties and feel the need to have other people with whom to talk. They are likely to be involved in social activities, and they may lose control quickly. Additional traits of people with high extroversion scores include irresponsibility, dominance, sensation seeking, and engagement in risk-taking behaviors. Individuals with low extraversion scores (a.k.a. introverts) are often characterized as reliable, somewhat pessimistic, and highly ethical. The biological correlates of extraversion include a high level of cortical arousal and general physiological arousal.

Individuals who score high on the Neuroticism scale (24 items) of the EPQ-R generally have a temperament reflective of negative affect. More specifically, they often possess high levels of anxiety and/or depression. These types of people may be frequently worried or nervous, often sleep poorly, and have high susceptibility to develop psychosomatic disorders. In addition, they may be overly emotional and react too strongly to events in their environment. Other traits that high scorers on the Neuroticism scale may have include feelings of guilt, moodiness, tenseness, obsessive thoughts, low self-esteem, and dependence. In terms of biological associations, it has been suggested that the basis for neuroticism is the sympathetic nervous system, which controls our "fight or flight" response to threatening environmental stimuli.

Self-report measures like the EPQ-R are, of course, subject to the honesty and accuracy of the respondent. Therefore, the EPQ-R also includes a "lie" scale (21 items) to detect inaccurate or socially desirable responding. If the respondent is not able to admit to a number of everyday human foibles or is trying to present him- or herself in an overly positive manner, the lie scale score will be high. When the lie scale score is high, the other scores are not interpreted.

The EPQ-R and its earlier versions have been used extensively in psychological research. That being the case, the psychometric properties of the EPQ-R have been the subject of much study. Studies of the psychometric properties of self-report questionnaires like the EPQ-R examine questions of reliability (i.e., are the scores repeatable or stable from one administration or time to the next?) and validity (i.e., do the scores really reflect levels individual differences in levels of the hypothesized construct—e.g., neuroticism—and not something else—e.g., anger?). Although the Neuroticism and Extraversion scales of the EPQ-R have received a substantial amount of empirical psychometric support, the Psychoticism scale has not. Specifically, scores on the Psychoticism scale have been shown to have low reliability. The construct of psychoticism has not been as ex-

tensively studied as neuroticism or extraversion, which may explain the psychometric weaknesses of the psychoticism scale.

In summary, the EPQ-R provides scores that allow for the clinical use of Hans J. Eysenck's P.E.N. model, which attempts to explain human personality variation. The EPQ-R has also been used extensively for psychological research. The extraversion and neuroticism scores have good reliability and validity for a variety of purposes. Scores on the psychoticism domain have been the focus of far less study, but even so it can be stated that they do not possess the same level of psychometric quality. The P.E.N. model is but one of many models used to explain and describe human personality, although it has enjoyed a prominent place among them. Perhaps the most important distinguishing characteristic of the P.E.N. model is the emphasis that P.E.N. supporters have placed on the biological basis of personality (see the earlier description of each personality factor). According to the leading P.E.N. researchers, personality is based in biology, and a personality factor can only be confirmed as such when biological markers or correlates are identified. This is in direct contrast to other personality models, like the Big Five Model or models based on "psychological type," where biological causes of personality are not required for the identification of a construct as a personality factor. Because P.E.N. theorists have placed this emphasis on biology, cross-species research has been more productive, even resulting in the thought-provoking notion that rats have the same three personality factors as humans!

FACE RECOGNITION

Face recognition is an important and arguably unique human ability. Some researchers assert that face recognition is specific and neurally encapsulated (Fodor, 1983) or "special" (Ellis & Young, 1989), whereas others describe face recognition as a general, well-practiced perceptual skill (Bushnell, 1998). Although face recognition is rapid and seemingly effortless, it involves several levels of analysis. Numerous studies have detailed the workings of this process, its failure, and its development.

Accuracy

Bahrick, Bahrick, and Wittlinger (1975) documented that adults could distinguish the faces of high school classmates from others long after graduation. Fifty years later, participants recognized 75% of classmates' faces. Even brief exposures lead to extremely accurate recognition, although studies of eyewitness testimony indicate that recognition is not perfect (Goldstein, 1977). Specific modifications to face recognition tasks may affect performance. For example, recognition accuracy decreases when faces are inverted relative to pictures of objects such as houses or dogs (Scapinello & Yarmey, 1970; but see Diamond & Carey, 1986).

Prosopagnosia

Failure to recognize faces, prosopagnosia, is a rare but fascinating disorder that yields information about mechanisms. Prosopagnosics fail to recognize faces of persons they knew before onset of the disorder and the faces of those encountered frequently afterwards. The cause appears to be damage to the occipito-temporal regions of the central visual system, especially in the right hemisphere. Although *prosopagnosia* is meant to describe a face-processing deficit, individuals with this diagnosis may have difficulty with any stimulus that requires specific and context-related recognition (Damasio, Damasio, & Van Hoesen, 1982). More generalized deficits may reflect more widespread damage.

Nonhuman Primates

Nonhuman primates also show face recognition, for both human and nonhuman primate faces. Humans and squirrel monkeys recognize upright human and great ape faces better than inverted faces (Phelps & Roberts, 1994). Gross, Rocha-Miranda, and Bender (1972) discovered that some cells in monkeys' temporal cortex were selectively responsive to stimuli such as hands and faces. Similarly, Perrett and colleagues (1984) found cells that were especially responsive to a particular human face often seen by the monkey. Single neurons in the primate temporal lobe visual cortex respond primarily to faces and differentially to familiar faces (Rolls, Treves, Tovee, & Panzeri, 1998). Such evidence suggests that mechanisms have evolved that allow for early steps in a facial recognition process without extensive learning.

Development

Initially, human infants attend preferentially to faces. Goren, Sarty, and Wu (1975) discovered that newborns would visually track facelike images further than images that contained facial features but in noncanonical patterns. Newborns also recognize their mother's face. Infants at 12 to 36 hours produced more sucking responses upon viewing an image of their mother's face compared to an unfamiliar face matched for eye color, complexion, and hair color and style (Walton, Bower, & Bower, 1992).

A major developmental question is whether children treat faces as sets of independent features or as unified wholes. Cashon and Cohen (1999) found that after repeated exposure to two unfamiliar faces, 7-month-olds treated a composite face that combined the internal features of the two faces as novel. This configurational effect disappeared when it was inverted, suggesting that infants (like adults) process an *inverted* face as a set of features.

Summary

Human adults are highly skilled in the face detection, discrimination, and recognition. Infants show similar skills, recognizing their mothers' faces when newborns and using configurational information to discriminate faces by 7 months. Unequivocal evidence that face recognition is "special" or simply expert is not yet available, although neurophysiological data are becoming increasingly useful.

FACE VALIDITY

Face validity refers to a characteristic associated with a psychological test and its individual items. Distinct from more technical types of validity, face validity is the appropriateness, sensibility, or relevance of the test and its items as they appear to the person answering the test. That is, do a test and its items look valid and meaningful to the individual taking the test? More formally, face validity has been defined as the degree to which a test respondent views the content of a test and its items as relevant to the situation being considered (Wiggins, 1973).

Three factors are important in the definition of face validity. First, face validity is based not on the judgments of psychologists or experts, but rather on the opinions of test takers who may be quite naive about the domain being assessed by the test. Second, face validity depends on the obviousness of the test item content (e.g., the test items may imply that a personality trait, such as neatness, is being measured). Third, the situation in which a test is given will influence face validity. Most important, however, in determining the face validity of a test or test item is the combination of these three factors. Consider the statement "Trying something new is scary," to which a test taker must answer either "true" or "false." If this item appeared on an employment test being given to job candidates who were applying to work for a manufacturing company, the applicants might feel that the test item is irrelevant or inappropriate for that testing situation (i.e., the item is not face valid). Further, if the entire employment test consisted of statements with similar content, then the test as a whole might be viewed as lacking face validity. Now, consider the same item being given on a test to patients newly admitted to a psychiatric hospital. For test takers in such a mental health setting, the test item might well seem to be quite appropriate and situationally relevant (i.e., the item is face valid).

Should test developers strive to construct tests that are face valid? The answer to this question depends on the test developer's theoretical orientation as well as on considerations of technical validity, public relations, and possible litigation.

The content of face-valid tests is readily identifiable by test takers and is susceptible to faking, either consciously or unconsciously. Test developers whose theoretical orientation emphasizes test respondent defensiveness (e.g., psychoanalytically oriented test developers), or test administrators who are employed in defensiveness-inducing situations (e.g., personnel or forensic settings) in which there is an assumption that individuals will not present themselves openly and honestly, believe that face-valid tests will result in inaccurate responses and, consequently, that such tests should be avoided. Alternatively, test constructors who possess a theoretical perspective that people will present themselves openly and honestly believe that direct, transparent (i.e., face-valid) tests are those of choice.

Research on technical validity has shown significant positive associations between face validity and test item accuracy (Holden & Jackson, 1979). Test items having face validity, on average, tend to be more technically valid or ac-

curate (i.e., they are better items because they tend to be more strongly associated with a relevant criterion) than those items not possessing face validity. Further, research also indicates that, in circumstances under which test takers have been asked to fake responses, face-valid items (which are supposedly more susceptible to faking) are no less accurate than items that are not face valid (Holden & Jackson, 1985). Although the positive association between face validity and technical validity is significant and stable, it is not perfect, and consequently, cautions are warranted. Face validity may be related to better test items, but it does not guarantee other, more technical and desirable forms of validity. Thus, the mere appearance of relevance or face validity (e.g., as regularly found in tests published in popular magazines) fails to ensure a test's accuracy. Furthermore, the absence of face validity does not necessarily mean that a test or its items are inaccurate.

The face validity of a test is an important factor for issues of public relations and litigation (Nevo, 1985). Psychological testing should not be an antagonistic and seemingly irrelevant exercise for test respondents. Cooperation and good rapport between testers and test takers is sound practice in all assessment circumstances. The presence of face validity enhances test takers' motivation and effort (Bornstein, 1996) and the perceived relevance of a psychological test. Further, face validity reduces the likelihood of feelings of depersonalization and resentment in the individual being tested. The absence of face validity (regardless of technical validity or accuracy) may result in feelings of anger and frustration and of being cheated. Such feelings may well be acted on, resulting in negative media publicity, public demands for the cessation of testing programs (e.g., in schools), labor-management conflict, or even costly legal proceedings.

FACTORIAL DESIGNS

A factorial design is one in which the effects of *two or more factors* are studied simultaneously. Because the factors are considered in the same design, both their individual effects (called *main effects*) and their joint effects (called *interactions*) on the dependent variable can be assessed.

Single-Factor Designs

First consider a design in which there is only one factor. Suppose an investigator wishes to assess the effects of fatigue on test performance by using three groups of subjects: low, moderate, and high fatigue. Because fatigue is the variable that is manipulated, it is referred to as the *independent variable* or *factor* in the design. The fatigue factor is said to have three *levels,* one for each fatigue group. More generally, the single factor in this experiment may be referred to as A and the levels as A_1, A_2, and A_3.

Test performance is measured for each participant and is referred to as the *dependent variable.* Even if the fatigue factor had no effect, we would not expect the mean test performance to be exactly the same at each level of fatigue, because of random variability. Analysis of variance (ANOVA) is a general statistical procedure for testing the null hypothesis that the population means at each level of a factor are equal.

Two-Factor Designs

We can change the one-factor design into a factorial design by adding a second factor, say, test difficulty, with levels low and high. More generally, we can say that a second factor B with levels B_1 and B_2 has been added to the design (see Table 1).

In this 3×2 factorial design (so called because factor A has thee levels and factor B has two), the effects of fatigue and test difficulty can be studied as well as their joint effects. There are six combinations of levels of fatigue and difficulty, each corresponding to a cell in the table. Now consider the idealized data presented in Table 1. We assume that there are equal numbers of participants in each condition and that there are no effects of random variability or measurement error, so that any differences obtained among groups will be due to *real* effects.

The number in each cell represents the mean test score for participants at the corresponding combination of levels of A and B. For example, the mean score for medium fatigue and low test difficulty is 70. The numbers outside the table are called *marginal* means, and they represent the means of rows and columns of the table.

Main Effects

If there is no error variability, we say that a factor has a main effect if the means of the levels of the factor are not all the same. In our example, there are main effects of both

Table 1. A 3 × 2 Factorial Design With no Interaction

	Level of Fatigue			
Test Difficulty	Low	Medium	High	Averages
Low	80	70	60	70
High	60	50	40	50
Averages	70	60	50	

Table 2. A 3 × 2 Factorial Design With an Interaction

	Level of Fatigue			
Test Difficulty	Low	Medium	High	Averages
Low	75	70	65	70
High	65	50	35	50
Averages	70	60	50	

fatigue and test difficulty. For test difficulty, the mean score for the low-difficulty test condition, 70, is 10 points higher than the average of the low and high difficulty levels, whereas the mean score in the high-difficulty test condition is 10 points lower. Therefore, the effects associated with the low- and high-difficulty conditions are +10 and –10. The corresponding effects for the low-, medium-, and high-fatigue conditions are +10, 0, and –10.

Interactions

In Table 1, the data are additive; that is, the effect of being in the A_1B_1 cell is the sum of the effects of being at level A_1 of A and level B_1 of B. However, in many cases particular combinations of levels of factors may have joint effects that cannot be obtained by adding the main effects of the factors. In Table 2 the marginal means, and hence the main effects for both factors are exactly the same as in Table 1. However, some of the cell means are different. The effect of the combination of high fatigue and high test difficulty (35 – 60 = –25) is not the same as the sum of the high fatigue and high test difficulty effects (–10 and –10). In this case there is a nonzero joint effect, and we say that there is a Difficulty × Fatigue interaction. There would be no Difficulty × Fatigue interaction if the differences between the low- and high-difficulty condition were the same for each level of fatigue.

Interactions and main effects are logically independent. Knowing whether or not there are A and B main effects does not tell us anything about whether or not there is an $A \times B$ interaction. It is possible to investigate interactions among factors only if they are considered in the same design.

Higher-Order Factorial Designs

In designs with more than two factors, there may be different kinds of interactions. If we have a design with three factors *A, B,* and *C,* we could have three *first-order interactions,* $A \times B$, $A \times C$, and $B \times C$. If we wished to consider, say, the $A \times B$ interaction, we could average over the levels of C. Similarly, if we wished to investigate the $B \times C$ interaction, we could average over levels of A, and so on. Higher-order interactions involve more than two factors. With factors *A, B,* and *C* it would be possible to have a second-order interaction, $A \times B \times C$. This would occur if, for example, the simple $A \times B$ interactions at each level of C were not all the same.

University of Massachusetts

FAMILY THERAPY

The field of family therapy began to burgeon in the 1950s, partially because those who were to become the early pioneers were not satisfied with the slow progress they made when doing individual therapy or psychoanalysis, and because they recognized that the impact that changes in the patient had on family members could be great. If the significant others had no place to discuss what was occurring and their reactions to it, they might sabotage treatment; therefore, it would be better if they were part of the process. Moreover, there were huge waiting lists at agencies after World War II, so seeing couples or families together seemed a justifiable way to cut the patient backlog. Earlier roots of the family therapy movement existed in the child guidance movement, even though in child guidance clinics a psychiatrist usually saw the child while a social worker saw the parent, concurrently and not conjointly, and conjoint sessions would be the model in the emerging field of family therapy. Another tributary was the early approach to social work with troubled, multi-problem families (Richmond, 1917); however, this often entailed home visits rather than having whole families come to the therapist's office, which was to evolve as the most frequent practice in the ensuing 40-plus years. (For histories of the field see Guerin, 1976; Kaslow, 1982, 1987; Kaslow, Kaslow, & Farber, 1999). Interestingly, since the early 1990s there has been a resurgence of the practice of home-based treatment, both in the United States and other countries, with poor and multi-problem families who are unable or unwilling to get to therapists' offices (Sharlin & Shamai, 1999).

The fact that the field of family therapy had come into its own was marked by the birth of the journal *Family Process* in 1961, and the field's status was solidified by the subsequent inauguration of at least half a dozen other major family journals in the United States and several dozen additional ones in numerous other countries during the 1970s and 1980s. Books on this mammoth topic also have proliferated exponentially. The United States has spawned two major organizations that are dedicated to the field of family therapy. The American Association for Marriage and Family Therapy (AAMFT) began in 1942 as the American

Association of Marriage Counselors, which reflected its focus then. It was not changed to AAMFT until the late 1970s. The American Family Therapy Academy (AFTA) began in the mid-1970s as the American Family Therapy Association. The Division of Family Psychology (#41) of the American Psychological Association (APA) began in the mid-1980s and now has several thousand members, and is about double the size of AFTA. The American Psychiatric Association (ApA) also has a separate unit focused on the family. Other countries have established similar national and regional organizations.

There are also two major international organizations devoted to this discipline: the International Family Therapy Association (IFTA), started in 1987, and the International Academy of Family Psychology (IAFP), inaugurated in 1990. Using organization memberships, journal subscriptions, and the number of books published annually as a quantitative measure of the field's importance and stature, we can conclude that family therapy/psychology is indeed thriving in many countries of the world.

Some of the fundamental tenets of family therapy that have evolved and continue to be salient include the following: (1) The members of a family constitute a system, with all parts interdependent and interrelated; (2) change in any part (member) of the system causes corresponding changes in all other members of the system; (3) families range on a continuum from dysfunctional, through mid-range, to quite functional and healthy; (4) some members of families seek to retain the existing homeostatic balance or equilibrium, whereas other members, usually the younger ones, try to alter that balance; (5) many dysfunctional families are characterized by rigid alliances, schisms, and secrets; (6) healthy families exhibit good problem-solving skills, integrity, and open communication styles; (7) boundaries between generations should be clear and should not be crossed inappropriately; and (8) some patterns are transmitted intergenerationally, and these can be detrimental or healthy, depending on the pattern. There are additional basic principles; the ones presented here comprise just a representative sample of the core tenets.

Over the years a variety of schools of family therapy have emerged (Becvar & Becvar, 1996). Each theory or school has had its major progenitor(s) and its second-, third-, and fourth-generation leaders and staunch followers (Kaslow et al., 1999). Each theory promulgates a somewhat different viewpoint as to the definition of therapy and how treatment should be conducted—that is, the process and techniques that it advocates. Each school is predicated upon ideas about what makes change occur, and most articulate the interventions to use, which should be consonant with the theory's underlying assumptions and beliefs (Goldenberg & Goldenberg, 1996; Nichols & Schwartz, 1995).

We have divided and organized the theories into four categories and subsumed the most prominent of the contemporary approaches under the heading that seems most appropriate. The various theories have fluctuated in popularity; once having waned, they occasionally experience a resurgence of interest and again come to occupy a central position within the spectrum of available explanatory theories of family dynamics, structure, and functioning. Different theories have adherents in different countries, depending on where they were generated initially, which leaders have come to that region to present workshops on their own approaches, and which therapeutic styles and methodologies are most compatible with their cultural context. Our typology follows (Kaslow et al, 1999).

- I. Transgenerational schools
  - A. Psychodynamically informed (including object relations approaches)
  - B. Bowenian
  - C. Contextual/relational
  - D. Symbolic/experiential
- II. Systems models
  - A. Communications
  - B. Strategic
  - C. Structural
  - D. Systemic
  - E. Brief and solution focused
- III. Cognitive and behavioral models
  - A. Behavioral
  - B. Functional
  - C. Cognitive-behavioral
- IV. Miscellaneous
  - A. Psychoeducational
  - B. Narrative
  - C. Social constructionist (including postmodern linguistic approaches)
  - D. Integrative (including comprehensive and multimodal models)

The field to date has witnessed the ascendance of a bevy of charismatic leaders, some of whom attain guru status and garner disciples. However, in the last two decades at least part of the field, noticeably the more research-trained psychologists, has pushed for analysis and validation of what works through both qualitative and quantitative research on process and outcome variables, reaching beyond what people believe works based mainly on clinical evidence and personal testimonials.

Another controversial area in the field is the issue of whether graduate and professional students should first be trained broadly, learning many of the theories and only then going on to gain greater knowledge and competence in one or several theories and a set of techniques they believe have greatest efficacy, or whether they should learn one theory and its accompanying techniques in depth before being exposed to multiple approaches. Some see this latter training model as akin to indoctrination with a catechism, yet others deliberately select such curriculum and model.

Family theoreticians and practitioners, supervisors, and

researchers continue to be drawn from the fields of psychology, psychiatry, social work, marriage and family therapy, sociology, counseling and guidance, and nursing. Such diversity enriches the field, yet it also contributes to interdisciplinary tensions and conflicts around licensing—that is, the issue of who can use the title and practice marriage and family therapy. These turf conflagrations are apt to continue.

Since we are all born into a family and grow up in our family of origin or an adoptive or foster family, and most people later move on to create their own families, the fascination with the family as a system and as a unit that merits professional and societal attention no doubt will continue unabated for many decades to come. Therapists of all disciplines and theoretical persuasions share this fascination and find doing family therapy challenging, stimulating, frustrating, rewarding, and quite gratifying.

FAST AXOPLASMIC TRANSPORT

Fast axoplasmic transport (also known as *fast axonal transport*) is defined as the movement of vesicles in the axon and dendrites of nerve cells at speeds that range between 200 and 400 mm/day. Vesicle transport occurs in both directions along the axon and dendrites. The fast speed of movement distinguishes vesicle transport from the transport of soluble proteins that move along the axon at speeds of 0.5–3 mm/day (slow axonal transport). Schematically, a nerve cell can be subdivided into a cell body (perikaryon), short-branched dendrites, and a long axon. The diameter of the axon is small compared to the diameter of the cell body and the axon can reach a length of many centimeters. Therefore the end of the axon or axon terminal is often located a long distance from the cell body. The membrane proteins of axoplasmic vesicles are synthesized in the cell body where the rough endoplasmic reticulum (ER) and Golgi apparatus reside. Therefore transport of vesicles into the axon is required to supply synaptic vesicles at the axon terminal and for axon survival and regeneration. Fast axonal transport is also the mechanism by which membrane components are returned to the cell body for degradation.

The diameter of vesicles that are transported in the axon ranges in size from very small (50 nm, e.g., synaptic vesicles) to very large (1,000 nm, e.g., multivesicular bodies). The transport of vesicles originating in the cell body and traveling toward the axon terminal is defined as *anterograde transport.* The transport of vesicles originating at the axon terminal and traveling toward the cell body is defined as *retrograde transport.* The vesicles in transit along the axon represent the cargo transported by molecular motors as they travel on filaments of the cytoskeleton. There are three types of cytoskeletal filaments in neurons, called neurofilaments (10 nm in diameter), microtubules (25 nm), and actin filaments (6 nm). Only the latter two types of filaments are known to function as tracks or rails on which molecular motors transport cargo. Molecular motors require chemical energy in the form of ATP (adenosine triphosphate) to transport vesicles, and therefore the proteins are called *ATPases.* Molecular motors are filament-type specific. Kinesin and cytoplasmic dynein are the molecular motors that transport vesicles along microtubules (Hirokawa, 1998), and myosin is the motor that transports vesicles on actin filaments (DePina & Langford, 1999; Mermall, Post, & Mooseker, 1998).

Microtubules are usually long filaments (> 25 μm) and have an intrinsic polarity due to the identical orientation of the tubulin subunits within the filaments. To distinguish the two ends of the microtubule, one is called the plus end (fast-growing end) and the other the minus end (slow-growing). All microtubules in the axon are aligned parallel to the long axis of the axon with their plus ends distal relative to the cell body. The molecular motor kinesin is a plus end-directed motor—that is, it transports vesicles toward the plus end of the microtubule or away from the cell body (anterograde transport). Cytoplasmic dynein is a minus end-directed motor and is responsible for vesicle transport from the axon terminal (retrograde transport). The specific type of motor attached to a vesicle determines the direction in which it will be transported in the axon. Kinesin has been

shown to be associated with synaptic vesicles, synaptic precursor vesicles, mitochondria, multivesicular bodies, and presynaptic membrane precursor vesicles. Cytoplasmic dynein has been shown to be associated with retrogradely transported vesicles in axons including early and late endosomes and lysosomes.
